Foreword

When I was asked by Jeff Posnick to write a foreword to his new book on orthognathic surgery I said yes, without hesitation. I have known and respected Jeff since he was an enthusiastic, curious, and very bright student at the Harvard School of Dental Medicine, class of 1977. These formative years as a student were instrumental in the subsequent development of his interests and career in craniofacial and orthognathic surgery. Jeff would attend the Children's Hospital Craniofacial Clinic on many a Friday afternoon where he would observe Joseph Murray, John Mulliken, and me interacting with complex craniofacial patients, their families, our students and residents and the rest of our team. From the beginning, I liked Jeff personally, and I developed a relationship with him because he was very attentive and asked many probing questions. He did this not to show off (as Harvard students have been known to do) but to satisfy his inherent curiosity and eagerness to learn. To this day, Jeff will occasionally call to discuss a case and ask for advice, not because he does not have his own ideas or because he does not know what to do, but to check with someone else to see if that person has something to add. This is consistent with his desire to obtain the best information to help each patient and to educate himself. When you give Jeff advice, he always has probing follow-up questions to test your knowledge and recommendations. I have very much enjoyed these interactions over the years, even when our opinions have differed. I also admire Jeff's persistent "sense of wonder" during his long career.*

Never having written a Foreword before, I considered the role of the Foreword and Foreword writer. I was surprised to find that most texts in surgical disciplines have a Preface or an Introduction written by the author, telling how the author became interested in the subject of the book and describing how the book came about. The Preface or Introduction may also contain a summary of the contents of the book. The less common Foreword, on the other hand, is a short introductory statement written by someone other than the author. The writer of a Foreword may be an expert in the field, an author of a similar book and may have a relationship with the author. Presumably, good things will be said about the book, and the author of the Foreword will tell the reader why reading the book is worthwhile. In this respect, the Foreword may be helpful to the publisher for the purpose of marketing.

The more I began thinking about the task at hand, the more onerous it seemed to become. There was no doubt in my mind that this book would be a major contribution to the field, as was Jeff Posnick's 2-volume book: *Craniofacial and Maxillofacial Surgery in Children and Adolescents*, Philadelphia, WB Saunders, 2000. Dr. Paul Tessier wrote in his Foreword to that book: "Thanks go to Dr. Posnick for his overall work and to the publisher for accepting such an abundance of images for printing. As we approach the year 2000 (which has no quantitative reality), this book is already a landmark in craniofacial surgery." M. Michael Cohen Jr. wrote a second foreword calling it a "tour de force" and noting that Jeff wrote 40 of 45 chapters, making it an unusual single-authored book relative to the primary subject. Well, *Orthognathic Surgery: Principles and Practice* is equally a "landmark" and a "tour de force" and there is no use in trying to say something clever about it. Anyone who reads this book will find that it speaks for itself: "*Res ipsi loquitur*."

As with *Craniofacial and Maxillofacial Surgery in Children and Adolescents, Orthognathic Surgery: Principles and Practice* is a single-authored, 2-volume set and therefore has a consistent format, writing style, and "personality" not usually achieved in a multi-authored and edited textbook. This makes it easier and more pleasant to read. The book is divided into seven sections: Basic Principles and Concepts; Planning, Surgical Technique, and Complications; Classic Patterns and Presentations of Dentofacial Deformities; Frequently Seen Malformations with Dentofacial Deformity; Cleft Jaw Deformities; Post-Traumatic Dentofacial Deformities; and Frequent Aesthetic Considerations in the Dentofacial Deformity Patient. Dr. Posnick wrote 39 of the 40 chapters. The first and only invited chapter is the wonderfully informative and entertaining contribution by Jeff's long-term friend and colleague, M. Michael Cohen Jr.: "*The New Perspectives on the Face.*"

Jeff Posnick is meticulous and pays obsessive attention to detail. Therefore, each chapter includes comprehensive background material presented with a scholarly review of the pertinent literature. The relevance of this background to the overall treatment planning, execution, and outcome of orthognathic surgery is revealed and all this is supported by the incredible, well-documented, and beautifully illustrated material from Jeff's personal experience and practice. This presentation allows the reader to benefit from Jeff's thinking and his triumphs, challenges, and difficulties.

It is not the role of the Foreword writer to summarize the book. However, I would like to describe the highlights of just two chapters to support my laudatory comments above. Chapter 2 is an account of the pioneers in orthodontics, oral and maxillofacial surgery, plastic surgery, and

*Mulliken JB: A Sense of Wonder, *Plast Reconstr Surg* 110:1353-1359, 2002.

craniofacial surgery. Jeff Posnick painstakingly chronicles the critical advances in these specialties that brought us to our current state. The chapter reads like an exciting novel. Not only is the history documented in referenced detail, but also anecdotes of personal relationships between these great leaders and personal communications regarding their thinking, ideas, triumphs, and tribulations are described. The chapter ends by thanking the pioneers for their contributions and an appeal to future generations of surgeons to take up the challenge of creating their own innovations.

Chapter 28 on hemifacial microsomia (HFM), a deformity in which I am particularly interested, is another example of the quality of this text. Jeff Posnick and I have some disagreements in this area, particularly regarding the natural progression of the deformity and timing of treatment. We also disagree about the potential benefits of operative correction during growth, i.e., in the mixed dentition stage. Nevertheless, this chapter is one of the most comprehensive treatises on the condition, what is known of the etiopathogenesis and all the significant issues related to the care of patients with this variable, and in my opinion, progressive facial asymmetry that you will find in one location. He has reviewed the pertinent literature, and presented and critically evaluated the available data. By doing this, he implies the importance of understanding the natural history of the deformity and the patterns of growth in the management of these patients. Jeff Posnick is also correctly cautious and skeptical about the use of distraction osteogenesis for early correction. My experience is somewhat different. However, Jeff presents the facts as he sees them, and the conclusions are debatable but fair.

Much has been written on the subject of orthognathic surgery from its history, basic biology and physiology of the operations, descriptions of the techniques, peer-reviewed outcome studies, to review articles and textbooks. The challenge in writing about a common subject is to bring new insights and information to the readers; to say something new or significant and not to simply say what has already been said. Jeff Posnick meets this challenge in *Orthognathic Surgery: Principles and Practice.* It is comprehensive, well referenced, data supported, and scholarly. Also of note is the amazing number of quality color illustrations, a credit to Jeff and to the commitment of the publisher.

I started this project on a beautiful, early summer weekend in Boston, thinking I would skim the chapters quickly for a few hours to get a feel for the book. Not by choice or plan, however, I spent the entire weekend reading the book; I could not put it down. I suspect the readers will have the same experience. This text should be required reading for all surgeons interested in orthognathic surgery.

Preface

The treatment of dentofacial deformities has come a long way since 1897 when Vilray Blair, with Edward Angle's coaxing, completed bilateral body osteotomies under chloroform anesthesia to setback a prognathic mandible and establish an improved occlusion. The 70-minute operation conducted at the Baptist Hospital in St. Louis, Missouri, also included placement of a custom gutta-percha interocclusal splint and application of intermaxillary fixation.

The field of orthognathic surgery advanced by small increments over the next 6 decades until Hugo Obwegeser executed what has now become the three classic orthognathic procedures: Le Fort I (maxillary) osteotomy with down-fracture and disimpaction; intraoral sagittal split ramus osteotomies of the mandible; and the intraoral oblique osteotomy of the chin. His published results in the 1950s and presentations throughout the 1960s disseminated this early work. The animal model research carried out by William Bell confirmed the safety of these osteotomies and set the stage for refinements in orthognathic procedures by practicing surgeons. During this same timeframe, Hans Luhr boldly challenged standard thinking of osteotomy and fracture healing and stabilization techniques with his concepts of rigid metal plate and screw fixation. Simultaneously, Paul Tessier's imaginative introduction of craniofacial surgery energized thinking concerning the reconstruction of all head and neck conditions.

Today, knowledge of how to safely improve the quality of life for the individual with a dentofacial deformity is extensive. The object is no longer limited to achieving short-term improved occlusion. Currently, the triad of improved quality of life by achieving long-term dental health, enhanced facial aesthetics, and an open airway represent standard thinking. There still remain limitations relating to the uneven geographic distribution of experienced dedicated clinicians and the financial barriers to the correction of dentofacial deformities. However, the value of treatment to improve lives is undisputed.

The last comprehensive textbook on the subject—*Surgical Correction of Dentofacial Deformities* edited by Bell, Proffit, and White (1980)—had a major impact on patient care and remains a landmark in the field. Since then, other published texts have been useful but not comprehensive. After setting the outline for this project, my initial intention was to have experts in the field make contributions. I soon realized this was impractical if a consistent and comprehensive level of cohesive knowledge on the subject was to be compiled in a timely manner. In writing this single-authored text (the exception being a chapter contribution by M. Michael Cohen Jr.), I enlisted the help of clinicians from a spectrum of specialties to read each chapter for accuracy, adequacy of depth, and readability. This included critiques from academicians, clinicians in practice, past surgical fellows, and residents in training. They came from a spectrum of specialties, including oral and maxillofacial surgery, orthodontics, periodontics, prosthedontics, speech pathology, otolaryngology/head and neck surgery, plastic surgery, anesthesiology, medical genetics, sleep medicine, radiology, psychology and psychiatry, and pathology. I am grateful for their suggestions, as each brought a different perspective and individual criticism. By clarifying current knowledge on the subject, I hope this text encourages quality care and further advances in the field.

I would also like to thank my patients who have allowed the use of their case studies as teaching instruments. The presentation of clinical problems and real-life solutions remains an invaluable way to convey this knowledge. Their contributions will no doubt minimize treatment errors and optimize results for future patients.

What Constitutes a Face?

Structural Definitions

There are several ways to view faces. Figure 1-1 shows two fish.[14] If two eyes and a mouth define a face, then fish have faces. They may have one or two nostrils, which are not connected to the mouth. However, water entering the nostrils does bathe the olfactory mucosa. Fish lack an ear canal, but the inner ear is present. Weber's bones connect the swim bladder to the inner ear, and sound is transmitted.[10]

Another definition requires evolutionary transformation of the skull, in which a face is recognizable in mammals, but not in fish, amphibians, or reptiles (Fig. 1-2). The jaw is suspended from the braincase in reptiles. Mammals, however, have three ear ossicles, a secondary palate separating the airway passage from the mouth, and vertical positioning of the dentary.[35]

Behavioral Definitions

All animals communicate with each other in various ways by tactile, chemical, visual, and acoustical signaling. Insects have heads, but do they have faces? Paper wasps *(Polistes dominulus)* signal their status to each other by the number of black splotches on their yellow faces (Fig. 1-3).[41]

Some define faces by the presence and use of facial muscles, which do not exist in fish, amphibians, reptiles, or birds. In contrast, mammals can suckle and later chew, supported by a muscular tongue and movable lips and cheeks (Fig. 1-4). Often, the muscles in the ears can change positions to aid in hearing; a movable nose for smelling and touching, and facial hair, the *vibrissae,* are associated with musculature and serve as tactile organs.[10]

For some, a behavioral definition must include facial expressions, which are found in various primates (Fig. 1-5), including humans (Fig. 1-6).[10]

Symbolic Definitions

The term *symbolism* has been defined in many different ways. Here, I define *symbolic transformation* as the ambiguous representation of two things by association or resemblance. Two examples are shown in Figures 1-7 and 1-8.[10]

Facial Perspectives and Stages in the Life Cycle

Box 1-1 summarizes all possible perspectives from which the face can be described; Box 1-2 lists all the stages in the

Evolutionary Considerations

Evolution of the Mammalian Brain

The evolution of the mammalian brain is based on the development of the neocortex (Fig. 1-13), which also resulted in a cranial shape that was different than that of the dinosaurs. The coexistence of dinosaurs and mammals and their competition during the Mesozoic era made mammalian neocortical development possible.[5]

Dinosaurs were large and had long life spans of about 100 years. In contrast, mammals were very small and had short life spans, which allowed them to evolve into many different species rapidly. Possibly, there were 50 generations of mammals during one dinosaur generation.

Mammals were nocturnal and hunted at night. With the development of the neocortex, mammals had an active lifestyle as well as acute hearing and smelling, which made insect prey easier to come by and made escape from predators easier as well. The end of the dinosaur era allowed mammals to evolve larger body forms.

Molecular Components in Primate Brain and Craniofacial Evolution

The gene *Microcephalin (MCPH1)* was first identified in its mutant form in which it causes primary microcephaly, but the normal gene was then adaptively found to be important in regulating brain size, and it continues to evolve in humans.[18]

Homozygous *ASPM* mutations also cause microcephaly. The normal gene may regulate neural stem cell proliferation

and/or differentiation, possibly by mediating spindle-cell assembly during cell division.[31]

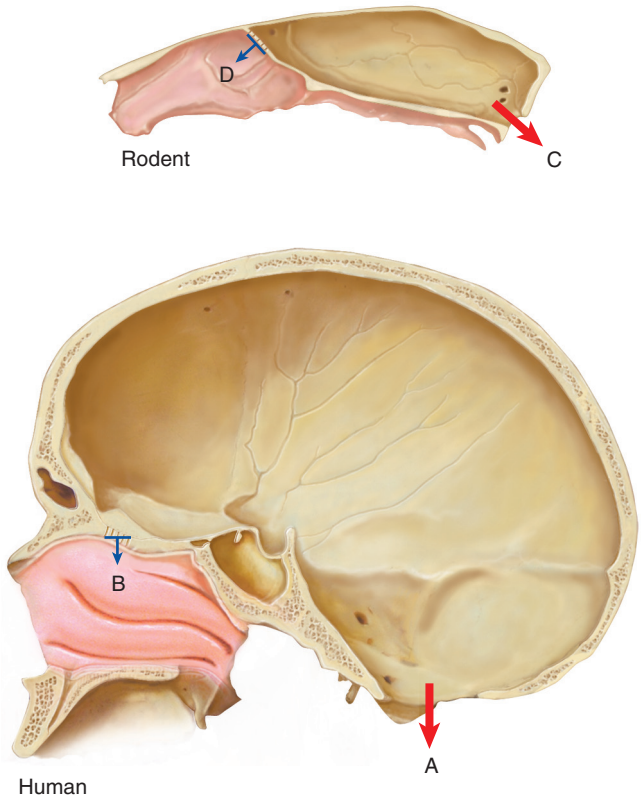
SIGLEC11, a gene involved in sialic acid biology, is expressed in high concentration in microglial cells in the human brain, but only occasionally in the cells of chimpanzees.[24]

The *Ret finger protein-like 1,2,3* (*RFPL 1,2,3*) genes on chromosome 22 are evolutionary forces that play a role in neocortical development.[3]

GTF2IRD1—a gene that, when mutated, causes craniofacial anomalies—has been shown in its normal form to be a regulatory determinant of craniofacial development.[39]

Comparison of Different Skulls

Figure 1-14 shows the orientation of the foramen magnum and the anterior cranial base in a rodent and a human. The foramen magnum is posteriorly placed in the rodent and vertically placed in the human. The anterior cranial floor and the cribriform plate face forward in the rodent and are vertically placed in the human.[16] Figure 1-15 shows a dog's



• **Figure 1-14** Orientation of the foramen magnum and the anterior cranial base in a human and a rodent. The anterior cranial floor and the cribriform plate face downward in the human *(B)* and forward in the rodent *(D)*. *Based on Enlow, 1968.*

skull compared to a Chevrolet Corvette in contrast to a human skull compared to a camper, indicating an expanded, upright forehead above the face.[17]

In Figure 1-16, expansion of the brain and a reduction in human facial prominence results in a flat facial profile compared with a smaller brain and a more protruding gorilla face, resulting in a sloping facial angle.[10] Figure 1-17 compares the growth pattern of a fetal chimp with that of a human fetus. Both fetuses look similar. However, compared with the adult chimp, the adult human more closely resembles its own fetal pattern. Neoteny—a slowdown in the growth rate with a delay in maturation—has occurred in human evolution.[23]

Comparison of *Homo sapiens, Homo neanderthalensis,* and *Homo floresiensis*

Evidence now shows that there are three separate species of hominins. Figure 1-18 compares the skulls of *Homo neanderthalensis* with *Homo sapiens*. The braincase of modern humans is relatively shorter, and the forehead is rounder, higher, and has a nearly vertical slope. Neanderthals have large brow ridges, projecting midface, elongated skull, occipital protuberance, a skull capacity 10% greater than that of modern humans, and a distinctive bony labyrinth not found in humans.[27] DNA sequence comparisons show that Neanderthals fall outside the variation of modern humans. Molecular divergence provides a date of over 500,000 years.[28]

Figure 1-19 contrasts the phenotypes of the different species of hominins. *Homo neanderthalensis* has an elongated skull with a larger endocranial capacity than in humans; a distinctive bony labyrinth not found in humans (not shown); a robust skeleton with a barrel-shaped ribcage; a long superior pubic ramus; long clavicles; thick, bowed femoral shafts; large patellas; and large, round, terminal phalanges (fingers). *Homo floresiensis* has a tiny skull with a small endocranial capacity (380 cm^3 to 430 cm^3), a chinless mandible, a diminutive body (~1 m in height), long arms in relation to the legs (arms hang almost to the knees), unusual shoulders, a wider pelvis than in humans, and large feet (more than 7½ inches long and out of proportion with the short lower limbs, flat feet, and a stubby great toe).[10]

The time spans of the three different species of hominins are (1) *Homo sapiens* from 500,000 years ago to the present time; (2) *Homo neanderthalensis* from 500,000 years ago until 30,000 years ago; and (3) *Homo floresiensis* from 95,000 years ago until 12,000 years ago. Thus, from 95,000 to 30,000 years ago, three different species of hominins occupied the earth at the same time.

Craniofacial Growth and Development

Comparative Skull Size with Age

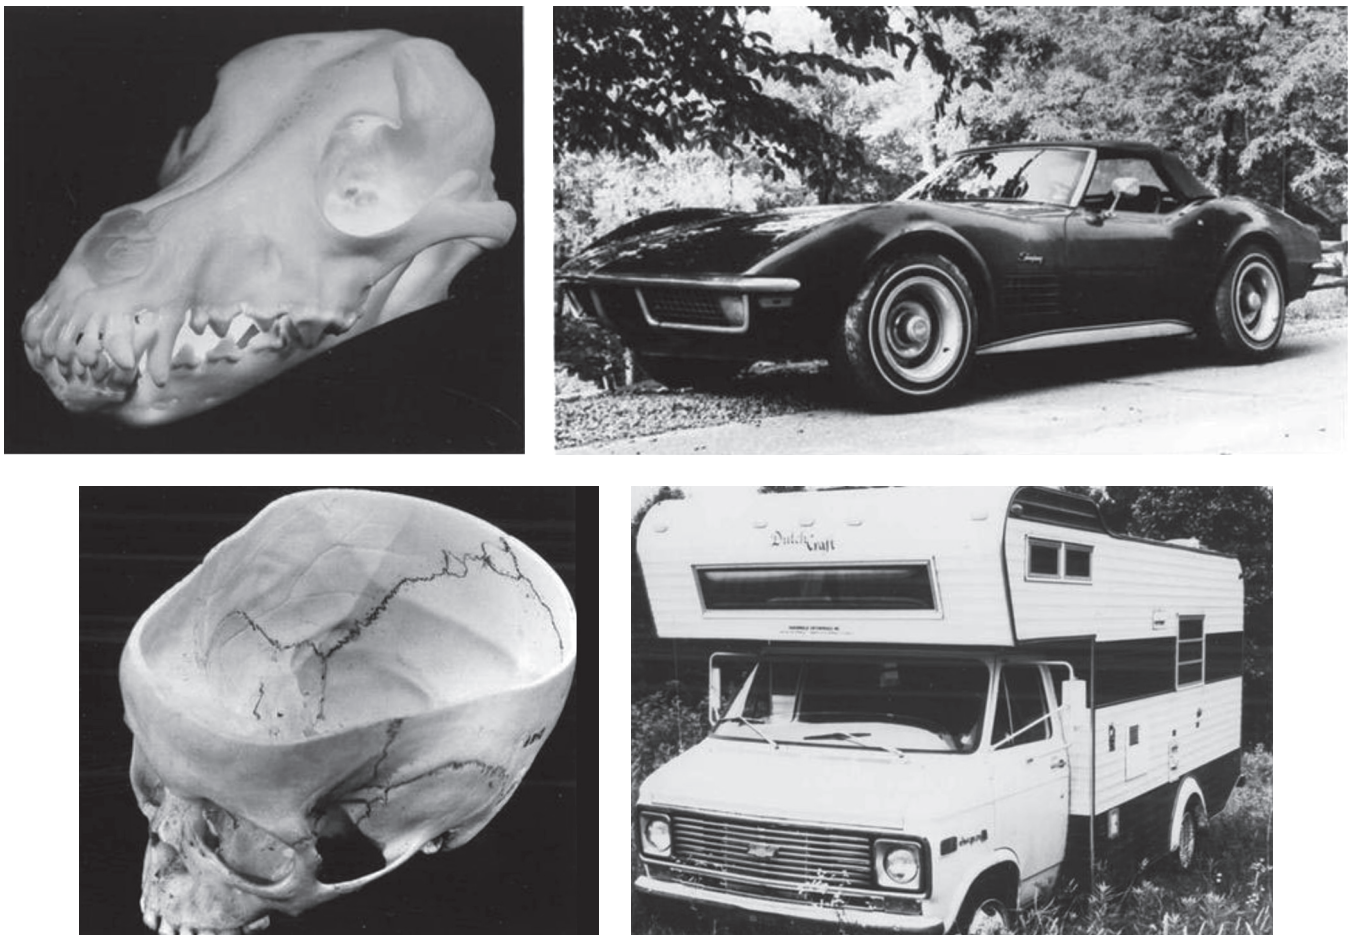
In the newborn skull (Fig. 1-20), the cranium and the orbits are relatively large, and the face is diminutive. In early childhood, the cranium and the orbits remain relatively large, but the eruption of the primary dentition enlarges the facial skeleton. In the adult skull, the facial skeleton is well-developed with relatively less prominence of the orbits and cranium. The ratio of the cranial volume to the facial volume changes during growth, and these ratios appear in Figure 1-20 under the skulls.[10]

Bone Modification with Age

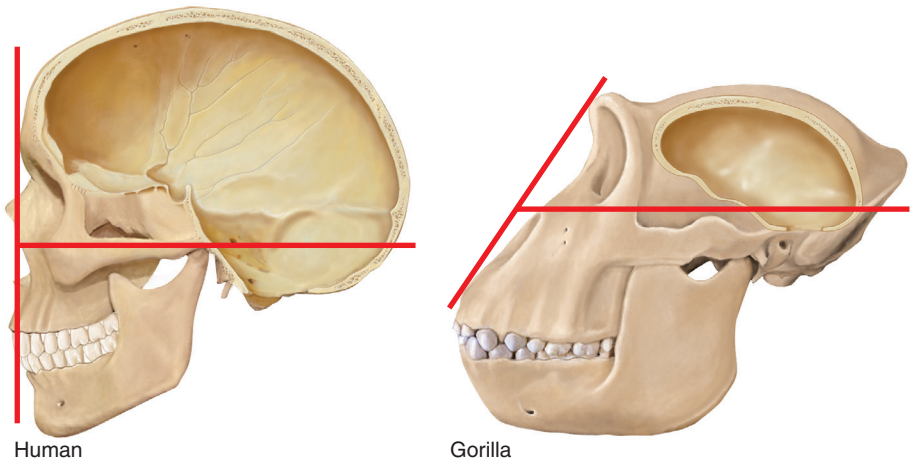
Bone modification of the craniofacial skeleton occurs normally with age (summarized in Table 1-1). Table 1-2 lists some examples of abnormal alterations in the craniofacial skeleton with age.[10]

Alterations in the Face with Age

The changing proportions of head size to body size are illustrated in Figure 1-21. From the 2-month-old embryo to the 22-year-old adult, the relative head size decreases significantly, but it is greatest in the fetus and the infant. Figure 1-22 illustrates line drawings of the facial profile showing alterations from 5 months of age to adulthood, with striking changes in the nose and chin with age.[10] The



• **Figure 1-15** **Top,** Lateral view of a dog skull compared to a Chevrolet Corvette; the face is anterior to the cranium. **Bottom,** Lateral view of a human skull compared to a camper; the expanded forebrain results in an upright forehead above the face. *From Enlow, 1990.*



• **Figure 1-16** Expansion of the brain and a reduction in the facial prominence of humans result in a flat facial angle compared with the smaller brain and more protrusive face of the gorilla, resulting in a sloping facial angle.

TABLE 1-1 Normal Growth and Modification of the Craniofacial Skeleton with Age

	Cartilaginous Growth	Sutural Growth	Skeletal Mass	Bone Remodeling
Infancy and Childhood	Active	Passive	Increases	Deposition greater than resorption
Adulthood	Absent	Absent	Remains the same	Deposition equals resorption
Old Age	Absent	Absent	Decreases	Resorption greater than deposition

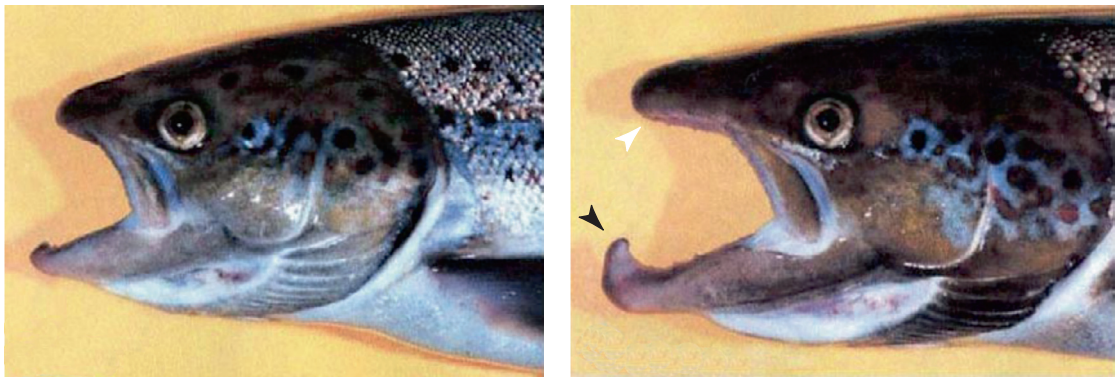
lower jaw in the male Atlantic salmon is extraordinary. There is rapid and pronounced growth *during adult life* (Fig. 1-23), when the *starving* salmon migrate upriver for spawning.[42]

Facial Asymmetry

Those psychologists who study faces and state that "beautiful faces are symmetric" don't know what they're talking about, because all normal faces are asymmetric. With respect to the normal face, subtle degrees of asymmetry become particularly evident when properly oriented frontal photographs are divided along the median plane and reprocessed, each side being paired with its mirror image (Fig. 1-24).[10]

The Skull as a Community of Bones versus the Skull as a Community of Joints

According to Pruzansky,[34] the skull is a community of bones separated by joints, but according to Moffett[32] the skull is a community of joints separated by bones. Which view is correct? They are simply different contexts in which to view the development of the skull.[10]



A B

Left side reprocessed with its mirror image

Right side reprocessed with its mirror image

• **Figure 1-24** Demonstration of the facial asymmetry that is so typical of everyone. *From Cohen, 2006.*

Pruzansky[34] stated the following:

"The skull is a community of bones and organ systems of diverse phylogenetic origin and variable patterns of development, altogether relating to several functions vital to the life and well-being of the organism. If in the course of development one member of this community is affected adversely, inevitably other parts will suffer."

• **Figure 1-25** Midface deficiency secondary to hypoplasia of the nasal capsule in achondroplasia. *From Cohen, 2000.*

Achondroplasia, caused by several *FGFR3* gain-of-function mutations (particularly Gly380 Arg[9]) illustrates what Pruzansky[34] meant (Fig. 1-25): if one member of the community is affected, inevitably other parts will suffer. In this case, the nasal capsule and cranial base, both cartilaginous in origin, have a secondary effect on membrane bones, because all craniofacial bones articulate with one another. Thus, in achondroplasia, the hypoplastic nasal capsule and short anterior cranial fossa result in midface deficiency.[7,9,10]

The skull may also be considered a community of joints separated by bones. Types of joints, known as *craniofacial articulations,* include synovial, cartilaginous, fibrous, and dental.[32] Table 1-3 summarizes craniofacial articulations together with their physiologic and mechanical functions and their remodeling responses.[10]

TABLE 1-2 Some Examples of Abnormal Alterations in the Craniofacial Skeleton with Age

	Abnormal Skeletal Condition	Pathologic Process
Infancy and Childhood	Achondroplasia	Bony midface deficiency secondary to hypoplasia of cartilaginous nasal capsule and cranial base
	Craniosynostosis	Premature sutural fusion by bone deposition
Adulthood	Acromegaly	Bone deposition dramatically exceeds bone resorption
	Hemifacial atrophy	Localized bone resorption exceeds bone deposition
Old Age	Paget disease of bone	Bone deposition exceeds bone resorption
	Senile osteoporosis	Bone resorption exceeds bone deposition

Dysmorphic Faces

Four different types of faces are contrasted in Figure 1-26: (1) the normal face; (2) Down syndrome with minor anomalies; (3) Crouzon syndrome; and (4) a bizarre prenatally determined face. Three views of Williams syndrome are illustrated in Figure 1-27. The combination of minor facial anomalies—strabismus, anteverted nares, and thick lips—are evident in all three patients. In contrast, the severe facial anomalies associated with holoprosencephaly—cyclopia, ethmocephaly, cebocephaly, and premaxillary agenesis—are shown in Figure 1-28.[6,8,10-12] A newborn with diprosopus—a double face with two nostrils, four eyes, two noses, and two mouths—is illustrated in Figure 1-29. The most bizarre case of all is shown in Figure 1-30. This patient is missing his lateral orbital walls, and he is able to pull his eyes apart laterally without ripping his optic heads from the back of his eyeballs. How he does this is mysterious, but I suspect he started doing this very early in childhood and gradually increased the distance over time.

The Outer Limits in Facial Surgery

The problems surrounding complete facial transplantation are technical, psychological, and ethical. Earlier, facial transplantation was rejected by many institutions, with the exception of the Cleveland Clinic's Institutional Review Board, and I have discussed the concept of facial transplantation and its associated problems elsewhere.[10] Although it was rejected earlier by the French National Ethics Advisory Committee, the door was left open for a severely disfigured woman bitten by a dog for which she received a lower facial transplant. Since then, at least seven facial transplants have been carried out. The result of a facial transplant after a gunshot wound is shown in Figure 1-31.

Making Blind People See Again

The cornea covers the eye globe and a narrow zone between the cornea and the conjunctiva known as the *limbus* (Fig. 1-32), which is a source of stem cells for corneal epithelium. In recent years, new techniques that can restore vision in certain types of blindness have come to the fore. In a surgical procedure called *limbal cell transplantation,* extraction of stem cells from the healthy contralateral eye of a patient or from a relative in the family is transplanted into a patient's eye with corneal degeneration, blindness, or some other ocular disease. The stem cells then differentiate into corneal epithelial cells and improve vision.[19] The limbus itself can be destroyed by chemical burns, by thermal burns, or by infection, which results in corneal stem-cell deficiency. However, it has been recently reported that a viable alternative source of cells for transplantation consists of limbal cells maintained in culture.[36] A biosynthetic cornea created from human collagen has also been developed. It mimics the protein's scaffolding and can be used to trigger regeneration of a patient's own corneal cells.[20]

Age-related macular degeneration is a major cause of blindness. Although there is no treatment for the avascular type, the neovascular type results from an imbalance in antiangiogenic and proangiogenic factors and can be treated. Intravitreal injection of VEGF inhibitors results in significant recovery of vision in 30% to 40% of patients.[40]

Leber congenital amaurosis is an inherited group of rod–cone dystrophies resulting in congenital blindness. One form caused by the *RPE65* gene accounts for 16% of the cases. Using rAAV as a vector for retinal gene therapy, a cannula is passed through the front of the eye and across the vitreous gel. Working copies of the gene are injected into the back of the eye. Maguire and colleagues[30] reported improvement in visual acuity for all patients.

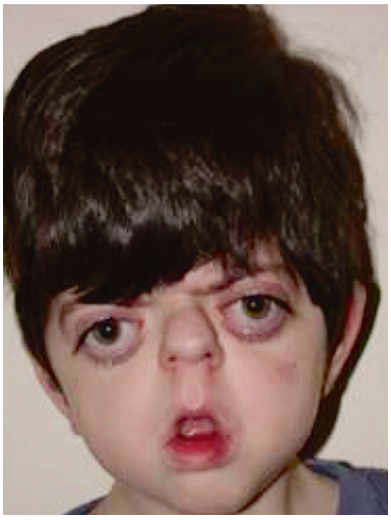
Several animal studies show great promise for future treatment. The development of retinal cell transplants has been studied in rabbits,[38] and retinal repair by transplantation of photoreceptor precursors has been studied in mice.[29]

Prosopagnosia

The ability to identify human faces is remarkable. Although the face ages with time, it is possible to instantly identify a face of someone who has not been seen for 25 or 30 years. An area in the brain that governs facial recognition is found

Normal face

Down syndrome



Crouzon syndrome

Severe prenatal anomaly

• **Figure 1-26** Four kinds of faces with different implications. A normal child's face is shown. Down syndrome involves many minor facial anomalies that are diagnostic. Crouzon syndrome is severe but can be treated successfully with surgery. There is no effective treatment for the infant with severe facial anomalies and hydrocephalus. *Based on the work of M. Michael Cohen Jr. Crouzon syndrome is by courtesy of Bonnie Padwa, Boston.*

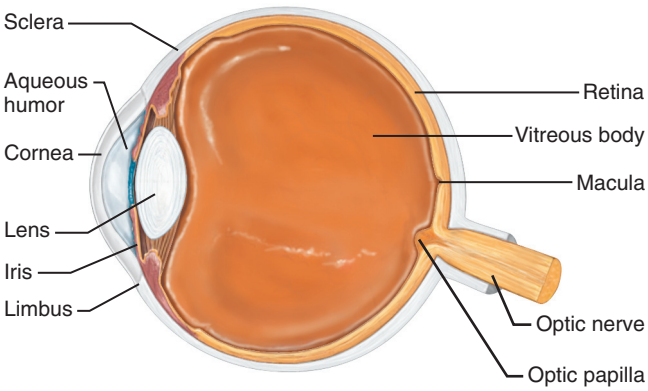
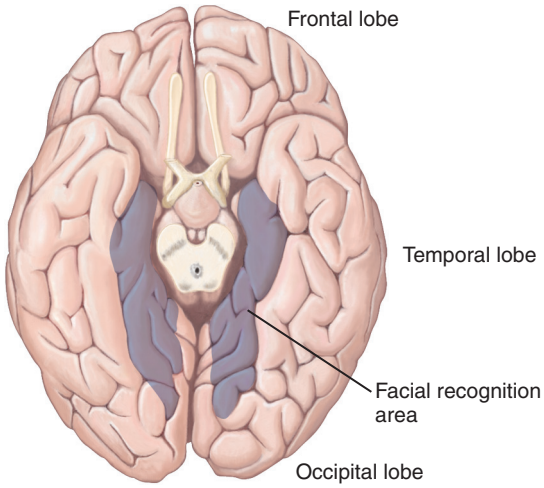
at the base of the cerebral cortex (Fig. 1-33). Any lesion that destroys this area impairs the ability to identify faces but has almost no other effects, although the dimming of vision may occur in some affected individuals. The patient can read, name objects, and match a full-face picture with a profile picture of the same person. Only the ability to recognize specific faces is lost; this is a neurological condition known as *prosopagnosia.* An affected man who cannot recognize his own wife can see her, but he can only recognize who she is when he hears her speak.[21] An epidemiologic study has found a prevalence rate of prosopagnosia of 2.47%; of 17 cases, 14 subjects had at least one first-degree relative with prosopagnosia.[26]



• **Figure 1-32** Eye globe, horizontal plane. Note the limbus. *Based on Cohen, 2006.*

The New Psychiatric Genetics

The brain, as part of the craniofacial complex, is associated with a number of psychiatric and neurodegenerative disorders. In medical genetics, we used to delineate newly recognized syndromes by describing them as single entities and then finding a Mendelian pattern, a chromosomal anomaly, or a teratogenic cause. After molecular genetics became established, it became clear that the same disorder might



• **Figure 1-33** Prosopagnosia. Note the area of the brain that governs facial recognition found at the base of the temporal and occipital lobes on both sides of the cerebral cortex. *Based on Geschwind, 1979.*

TABLE 1-3 Craniofacial Articulations

Type of Articulation	Example	Physiological Function	Mechanical Function	Remodeling Response
Synovial	Temporomandibular joint	Jaw movement	Resists compression and shear to some extent	Limited, avascular
Cartilaginous	Cranial base synchondroses	Active growth	Resists compression	Limited, avascular
Fibrous	Cranial sutures	Allows passage through narrow birth canal; growth secondary to brain enlargement	Respond to tension	Great, vascularized
	Facial sutures	Mastication	Sutures remain patent until old age; shock absorbers for forces of mastication	Great, vascularized
	Periodontal fibers	Eruption of teeth; anchoring support of teeth	Responds to tension, compression, and shear	Great, vascularized
Dental	Occlusal and interproximal articulations	Mastication and speech	Subject to compression and shear	None, acellular

have causative mutations in several different genes on different chromosomes. For example, Biedl-Bardet syndrome can be caused by mutations in 14 different genes, all on different chromosomes. Thus, we learned that what appeared to be a single disorder was etiologically heterogeneous.

Because psychiatric thinking began by attributing behavioral problems to earlier psychological events, it was the last bastion to be stormed by molecular genetics. Behavioral disorders are now being delineated at a molecular level, but, like the early delineation of physical genetic disorders, progress in psychiatric genetics only accounts for a small percentage of cases at present. Disorders with molecular findings include intellectual disability, schizophrenia, bipolar disorder, Alzheimer disease, autism, Parkinson disease, Huntington disease, and frontotemporal dementia.[13]

Artistic Perspective

Figure 1-34 compares two Renaissance paintings: a Florentine *Portrait of a Man with a Medal of Cosimo the Elder* by Botticelli and a Venetian *Portrait of Jacopo Soranzo* by Tintoretto. The difference in painting style is striking. In the Florentine painting, the outlines of the face are sharply drawn with a three-dimensional sculptural quality together with a sense of palpability. In contrast, in the Venetian painting, the lines of the face are soft and less distinct but with a sense of atmosphere surrounding the figure.[2]

Pioneers in the Field of Orthodontics

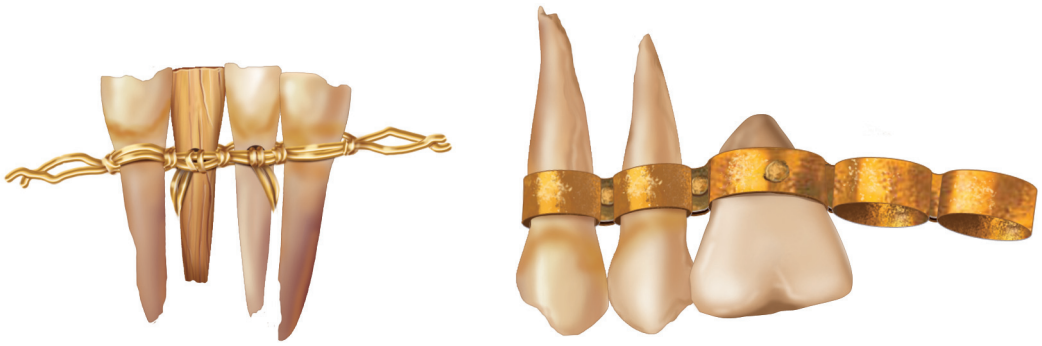
Background

Orthodontic appliances that are somewhat primitive but surprisingly well-designed for their time have been found in Ancient Greek written materials.[8] Four Etruscan specimens of young adult women dating back to 900 B.C. that specifically demonstrate appliances on the teeth have also been recovered.[23,208] The orthodontic type appliances are gold bands around teeth that are adjacent to an edentulous gap. The appliances appear to be for the purpose of managing the space left by tooth loss earlier in life (Fig. 2-1).[209] In addition, the Ancient Greek scholars Hippocrates and Aristotle both have writings that discuss various ways to straighten teeth and to treat various dental conditions.[20,51] Knowledge of dental extractions carried out for the purpose of mechanically straightening the remaining teeth was also reported by Leonardo da Vinci during the High Italian Renaissance.[166] The bandolet or bandeau, which was created in 1723 by Pierre Fauchard of France, was the first documented dental arch expansion appliance (Fig. 2-2).[202] It consisted of a heavy maxillary labial arch wire to which the teeth were ligated.[202] The term *orthodontia* is said to have been coined in 1841 by Lafoulon, and it appeared in the book about malocclusion written by J.M. Alexis Schange.[11,157,203]

In 1858, perhaps the first formal article on orthodontics published in a medical journal was written by Norman W. Kingsley (Fig. 2-3). By the 1880s, Norman Kingsley's *Treaties on Oral Deformities as a Branch of Mechanical Surgery* systematically described the current techniques of the day for the repositioning of teeth (Fig. 2-4).[109] Kingsley was among the first to fully describe how extraoral forces (e.g., headgear) could be used to correct protruding maxillary anterior teeth. His emphasis was primarily on the alignment of the anterior maxillary teeth in an attempt to improve facial appearance. To Kingsley, the extraction of teeth for the purpose of uncrowding and to reduce the protraction of the incisors was acceptable practice. Details of how the upper and lower teeth articulated with each other (i.e., occlusion) were of secondary importance. He used a wide variety of apparatus to reposition the anterior teeth, including wires, bands, custom palatal plates, elastics, wedges, linen twine, rubber tubing, leathers, gold bands, and vulcanite. Impressions of the teeth and dental models were used during planning and for the precontouring of labial placed wires. The use of an external apparatus placed over the top of the head and then either secured to the chin or held with bands secured to the maxillary incisors became part of his everyday practice (Fig. 2-5).

Kingsley's basic principles for the mechanical alignment of the teeth can be summarized as follows:

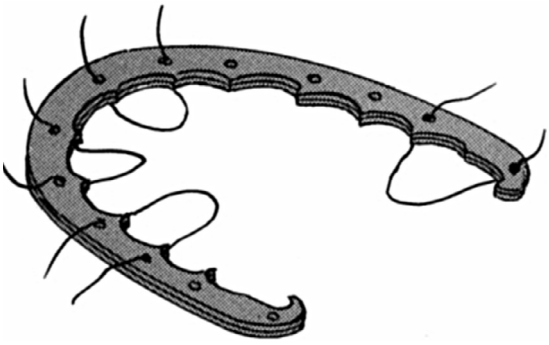
- The positioning of the six maxillary anterior teeth with regard to each other and in relationship to the lip is essential for facial aesthetics.
- The contact of a certain number of maxillary and mandibular posterior teeth, at least on one side, is important for the grinding and mastication of food.



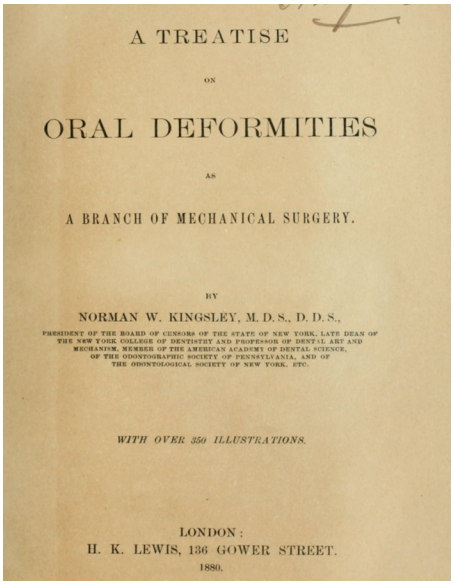
A Ancient Grecian appliance

B Ancient Etruscan appliance

• **Figure 2-1 A,** A drawing of the anterior mandibular dentition in a mummy specimen from ancient Greece (approximately 1000 B.C.) currently housed in the Archaeological Museum in Athens, Greece. A gold wire was used to tie teeth together and to band others to support replacements. The use of human, animal, carved wood, bone, or ivory for replacement teeth was practiced by the ancient Grecian society. **B, A** drawing of an ancient Etruscan orthodontic appliance found on the maxilla of a mummy in a tomb (approximately 700 B.C.), which is currently at the Civic Museum in Cornet, Italy. It demonstrates gold soldered rings and rivets to hold dental replacements as a bridge. The specimen has two natural teeth, one riveted oxtooth and four spaces for others



• **Figure 2-2** Illustration of the "bandolet" bandeau, which was created in 1723 by Pierre Fauchard of France. This was the first documented dental arch expansion appliance.



A TREATISE

ON

ORAL DEFORMITIES

AS

A BRANCH OF MECHANICAL SURGERY.

BY

NORMAN W. KINGSLEY, M. D. S., D. D. S.,

PRESIDENT OF THE BOARD OF CENSORS OF THE STATE OF NEW YORK, LATE DEAN OF THE NEW YORK COLLEGE OF DENTISTRY AND PROFESSOR OF DENTAL ART AND MECHANISM, MEMBER OF THE AMERICAN ACADEMY OF DENTAL SCIENCE, OF THE ODONTOGRAPHIC SOCIETY OF PENNSYLVANIA, AND OF THE ODONTOLOGICAL SOCIETY OF NEW YORK, ETC.

WITH OVER 350 ILLUSTRATIONS.

LONDON:
H. K. LEWIS, 136 GOWER STREET.
1880.

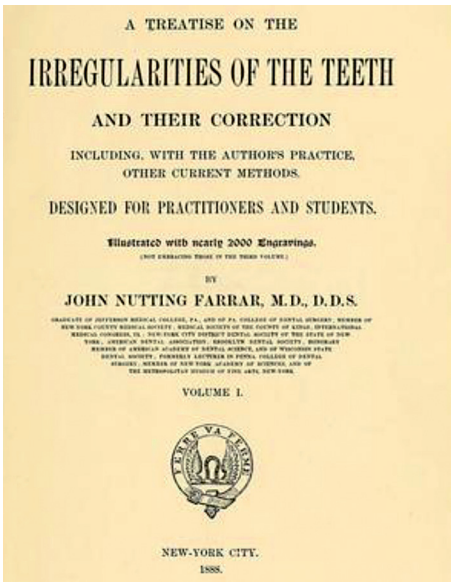
• **Figure 2-4** Norman Kingsley's text entitled *A Treatise on Oral Deformities as a Branch of Mechanical Surgery,* which was published in 1880.

• **Figure 2-3** Photograph of Norman W. Kingsley (1829-1913).

- All other teeth are potentially expendable, depending on the effort required by the clinician for straightening and the individual's desire to maintain them.
- From both a mastication and an aesthetic perspective, there is no particular need for the maintenance of all 32 teeth or to achieve a specific and detailed way of the upper and lower teeth occluding with one another.

Dr. Kingsley also commented on facial aesthetics, stating that "the eye soon tires of the stiffness and formality of unbroken uniformity, and is only permanently pleased with the beauty which comes from graceful variation."[109] He acknowledged the occurrence of jaw deformities when he said that "[a] lack of harmony between the maxilla and mandible is occasionally seen. For instance, when the

• **Figure 2-5** Headgear designed and used by Norman W. Kingsley. According to Kingsley, "I sat to work to make an apparatus that would pull the lower jaw back. As you can see from the photograph taken at the time she was wearing the apparatus, it consists of two parts. For the lower part, I made a brass plate to fit the chin, having arms with hooked ends reaching to a point just below the point of the chin. These arms were arranged in such a way that the distance between them could be altered at will by simply pressing them apart or to gather. The upper part consisted of a simple network going over the head and having two hooks on each side, one hook being above and the other below the ear. When the apparatus was completed and in use, there were four ligatures of ordinary elastic rubber pulling in such a way as to force the lower jaw almost directly backward." *From Kingsley NW:* A treatise on oral deformities as a branch of mechanical surgery, *London, 1880, H.K. Lewis, pp 137, Figure 68.*



A TREATISE ON THE

IRREGULARITIES OF THE TEETH

AND THEIR CORRECTION

INCLUDING, WITH THE AUTHOR'S PRACTICE, OTHER CURRENT METHODS.

DESIGNED FOR PRACTITIONERS AND STUDENTS.

Illustrated with nearly 2000 Engravings.

BY

JOHN NUTTING FARRAR, M.D., D.D.S.

VOLUME I.

NEW-YORK CITY.

1888.

• **Figure 2-6** John Nutting Farrar's two-volume illustrated text entitled *A Treatise on the Irregularities of the Teeth and Their Correction,* which was published in 1897.

• **Figure 2-7** Photograph of Edward H. Angle (1855-1930).

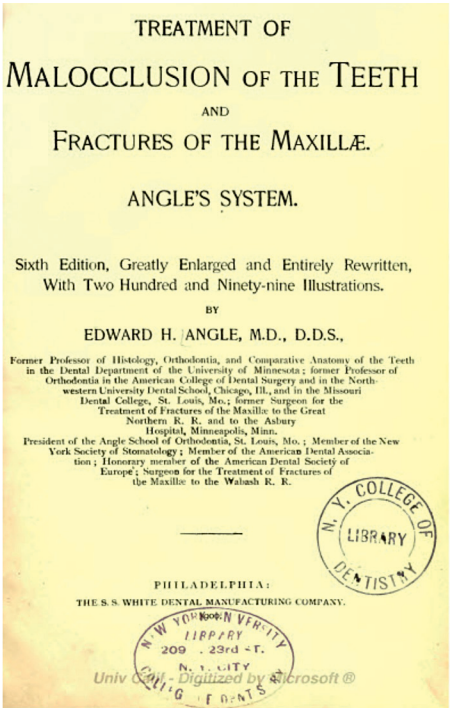
mandible is very large and massive or unusually small in comparison to the upper jaw. When present, this will interfere with the harmony of the surrounding parts of the face."[109]

In 1897, J.N. Farrar published a two-volume illustrated text entitled *A Treatise on the Irregularities of the Teeth and Their Corrections* (Fig. 2-6).[12] In that text, he also demonstrates detailed orthodontic appliances, and he was among the first to suggest the advantages of mild (rather than heavy) force applied at intervals to effectively move the teeth.[10]

Edward H. Angle

It was common practice through the later half of the 19th century to extract the teeth in response to most dental problems.[9,60] Restorative dentistry was generally not the first choice for the management of "toothaches." Most adults at that time (i.e., the 1880s) did not have a full complement of teeth nor was there much stigmata associated with partial edentulism.[210] Details of how the teeth occluded with each other seemed important only when establishing how upper and lower dentures were to meet so as to prevent loosening or mobility when wearing them and to improve chewing ability. It was a natural extension of this thinking for a prosthodontic-trained dentist like Edward H. Angle to develop a more holistic concept regarding the importance of the occlusion of the natural dentition (Fig. 2-7).[5-8] During his career, Angle taught prosthetics at the University of Minnesota (Minneapolis, Minn), Northwestern University Dental School (Chicago, Ill), and the Missouri Dental College (St. Louis, Mo). Dr. Angle's interest in dental occlusion and his ingenuity and dedication with regard to the correction of malocclusion led to the development of the specialty that we now call "orthodontics."

Angle's textbook, *Treatment of Malocclusion of the Teeth,* was first published in 1887 (Fig. 2-8).[6] It went into seven much-revised editions, and it laid the foundation for the modern specialty of orthodontics. The publication of Angle's classification of malocclusion during the 1890s was a key step in the development of orthodontics (Fig. 2-9).[42,43]



TREATMENT OF

MALOCCLUSION OF THE TEETH

AND

FRACTURES OF THE MAXILLÆ.

ANGLE'S SYSTEM.

Sixth Edition, Greatly Enlarged and Entirely Rewritten, With Two Hundred and Ninety-nine Illustrations.

BY

EDWARD H. ANGLE, M.D., D.D.S.,

Former Professor of Histology, Orthodontia, and Comparative Anatomy of the Teeth in the Dental Department of the University of Minnesota; former Professor of Orthodontia in the American College of Dental Surgery and in the North-western University Dental School, Chicago, Ill., and in the Missouri Dental College, St. Louis, Mo.; former Surgeon for the Treatment of Fractures of the Maxillæ to the Great Northern R. R. and to the Asbury Hospital, Minneapolis, Minn. President of the Angle School of Orthodontia, St. Louis, Mo.; Member of the New York Society of Stomatology; Member of the American Dental Association; Honorary member of the American Dental Society of Europe; Surgeon for the Treatment of Fractures of the Maxillæ to the Wabash R. R.

• **Figure 2-8** Dr. Angle published a comprehensive text entitled *A Treatment of Malocclusion of the Teeth and Fractures of the Maxillae,* the first edition of which was published in 1887. It went into seven revised editions, and it laid the foundation for the modern specialty of orthodontics.

Angle introduced the first precise and simple definition of the normal human occlusion of the natural dentition. He postulated that a key aspect of how the teeth should fit together was the positioning of the maxillary first molars. He then went on to describe three classes of malocclusion that were based on the occlusal relationships of the first molars:

Class I: There is a normal relationship of the molars, but the line of occlusion is incorrect as a result of malposed teeth, rotations, or other causes.

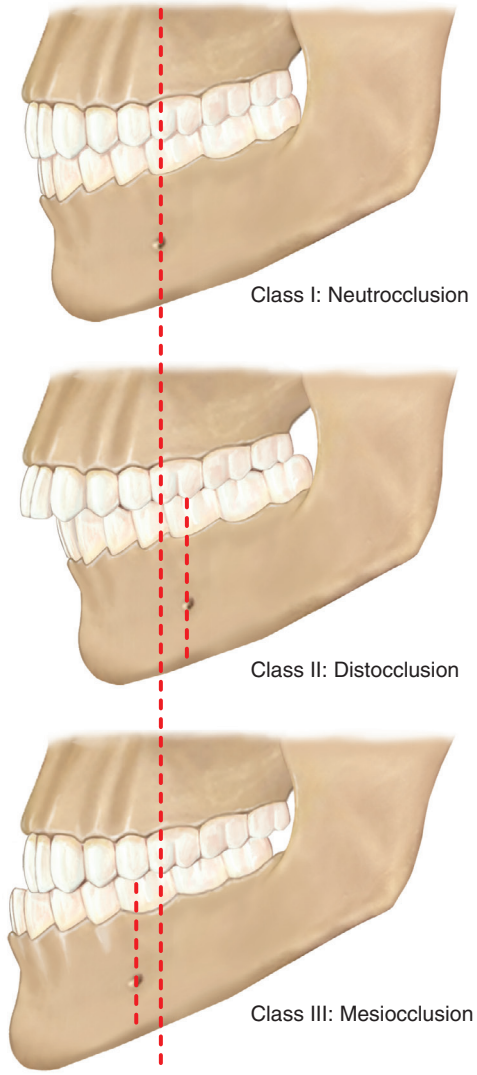
Class II: The lower molar is distally positioned relative to the upper molar, and the line of occlusion is not specified.

Class III: The lower molar is mesially positioned relative to the upper molar, and the line of occlusion is not specified.

Angle's classification actually has four classes:

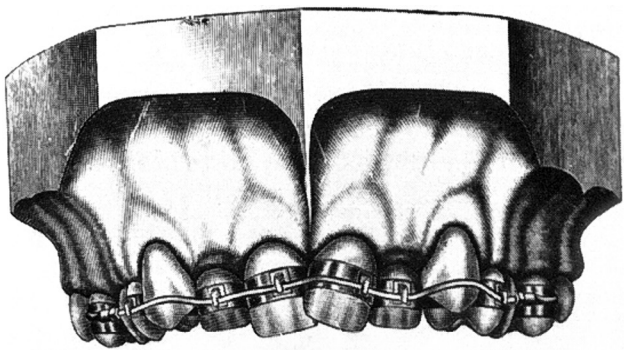
- Normal occlusion (Class I, with a normal line of occlusion)
- Class I malocclusion
- Class II malocclusion
- Class III malocclusion

Normal occlusion and Class I malocclusion share the same molar relationship, but they differ with regard to the arrangement of the other teeth relative to the line of occlusion. The line of occlusion may or may not be correct in Class II and Class III.

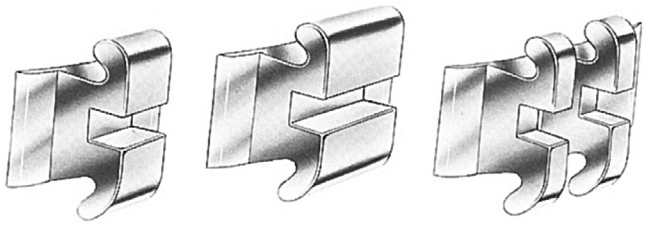


• **Figure 2-9** Angle described three classes of malocclusion based on the relationships of the first molars: Class I, Class II, and Class III.

By the early 1900s, orthodontists no longer just aligned irregular teeth in each arch.[175,218] The practice had now evolved into the treatment of malocclusion (i.e., how the upper and lower teeth align with each other). Angle's philosophy was to achieve a specific relationship between the upper and lower teeth for each patient. Since Angle's precisely defined dental relationships also required a full complement of teeth in each arch, the maintenance of an intact dentition became an important component of orthodontic treatment. Angle and his followers strongly opposed extraction for orthodontic purposes.[69] In an attempt to achieve the three-axis control of tooth movement, Angle introduced the *ribbon arch* (Fig. 2-10).[70] He then devised the *edgewise appliance* to overcome the weaknesses of the ribbon arch (Fig. 2-11). The Angle reoriented bracket slot was designed to control the bodily movement of teeth and to limit tipping.[135] Angle also heavily relied on the use of intraoral



• **Figure 2-10** The ribbon arch appliance, which was introduced by Angle in 1916. The vertical slot in the bracket accepts either round or rectangular wire, which in turn is held in place by a locked pin.



• **Figure 2-11** The edgewise bracket attachment comes in a variety of modifications. The original single bracket *(left)* has been widened for molar teeth and for greater rotational control *(center)*. The twin edgewise modification *(right)* is available in different widths, and it is used most frequently because of its greater versatility, its reduced frictional component, and its adaptability to various light-wire techniques.

rubber bands and limited the use of extraoral appliances (e.g., headgear) as much as possible.

Angle was among the first to state that jaw discrepancies exist in some individuals and that these discrepancies will prevent the achievement of a normal occlusion. He then acknowledged the need for jaw-straightening surgery. In Chapter 14: Operative Surgery of the sixth edition of Angle's textbook, he states that the use of appliances to move teeth may be properly called *conservative surgery* to distinguish it from more bold or aggressive operations involving the use of cutting instruments, which were designated as *operative surgery*. He states the following: "While such operations [mandibular osteotomies] should probably be employed only as auxiliary to the conservative method, they are doubtless destined to play an more important part in the practice in the future."[6]

Dr. Angle worried that no technique that relied solely on tooth movement could establish the appropriate relationships of the teeth or truly improve the facial lines in cases involving the severe overdevelopment of the inferior maxilla [mandible].[6] He felt that these cases may be successfully treated by removing a section of bone from each of the lateral halves of the mandible. At the time, the removal of a single complete section of the jaw had been reported for cases involving such conditions as ankylosis, tumors, and gunshot wounds, but Dr. Angle was unable to find information about the removal of complete sections from each of the lateral halves of the mandible. This idea was discussed by Dr. Angle with various surgeons and dentists and determined to be feasible. His proposal involved the following[6]:

- Careful photographs should first be taken of the patient.
- Two accurate models should be made of the lower dental arch, and one should be made of the upper.
- One of the plaster models of the lower jaw should then be sawed through and the sections removed.
- The positions and extent of the sections should be carefully experimented with until the three remaining sections of the model could be made to best harmonize with the upper arch so that the teeth may be in best possible occlusion with those of the upper jaw.
- The sections of the plaster model should then be cemented or waxed together.
- Over this reconstructed model, a vulcanite or metal splint should then be formed.
- With the use of careful comparisons and measurements of the reconstructed model as compared with the unchanged model, the exact size and form of both resections of bone to be removed can be determined so that there need be no guessing as to the relationships of the bone. In this way, complete apposition of the cut ends can be made.
- Because there is a lingual inclination of the lower incisors in all cases of mandibular prognathism, the sections of bone to be removed must not be parallel on their sides but instead more or less wedged or V-shaped to gain the best positions for the occlusion of the incisors as well as for the appearance of the chin.
- The degree of variation from the parallel of the lines of bone resection must be determined by the conditions that are present (i.e., patient variation).
- Because the operation must be skillfully performed, the most rigid support should be given to the reconstructed jaw. This technique (i.e., a cap splint over the teeth) should give more rigid support than is possible with the crude, unstable, and unmechanical plan of wiring the ends of the bone together, which is so often employed for the reduction of fractures.

According to Dr. Angle, "The question most often raised by dentists in discussing the practicability of an operation as outlined above was the uncertainty as to union of the bones and as to impairment of vitality of the teeth in the anterior segment [of the mandible]."[36] However, Dr. Angle helped with the overcoming of these concerns via two case reports that were presented in his textbook, *Treatment of Malocclusion of the Teeth and Fractures of the Mandible: Angle's System*[6] (pp 173-184):

First Patient (Operation)

June 23, 1897, the author [Dr. Angle] assisted the late Professor Henry H. Mudd in one of these operations performed at St. Luke's Hospital, St. Louis, upon Ms. M.J. of Arkansas, a delicate girl, 13 years old. She had likely suffered with generalized sepsis at 3 years of age

with the mandible becoming fixed and firmly closed [temporomandibular joint ankylosis]. The upper jaw was normal in size and contained a full complement of teeth. The lower jaw was deformed. The ramus of the jaw on each side passed downward and backwards so that the angle of the jaw came a little behind rather than in front of the vertical line dropped from the lobe of the ear. The arch of the lower jaw was broad and the incisor teeth were impinging the surface of the palate. The only point of entrance for food was the opening under the arch of the hard palate above the incisor teeth of the lower jaw.

To free the body of the jaw so that the mouth might be opened, a triangular segment with the base downward and the apex upward and forward was removed from the angle of the jaw on each side. A complete section of the bone was thus removed on each side to make false joints at the junction of the ramus and the body of the mandible. When the bone was separated, the tongue and jaw dropped down, making respiration difficult. An urgent tracheostomy was made. Wire ligatures were used to establish IMF [intermaxillary fixation]. This pulled the tongue and neck muscles superior and anterior, and established a good airway. The ligatures were occasionally removed in the ensuing weeks to allow movement of the jaw and establish a hinge joint instead of osseous union in the ramus regions of the mandible. Unfortunately, the patient was lost to follow-up several weeks later without permanent record of how things turned out.

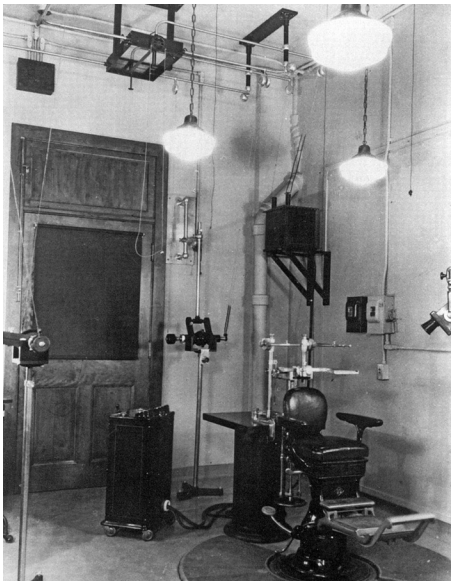
Second Patient (Operation)

A double resection [of the mandible] for the purpose of shortening a prognathic mandible was performed successfully at the Baptist Hospital in St. Louis [Dr. Vilray Blair was the surgeon, and the procedure was performed on December 19, 1897]. Such an operation might at first seem formidable, but there is no reason why, if skillfully performed according to modern aseptic methods of surgery and the plan is indicated, that clean smooth ends of the bone should not unite at least as readily as they do in the common cases of double [mandibular] fractures and the result being nearly ideal.

Holly Broadbent

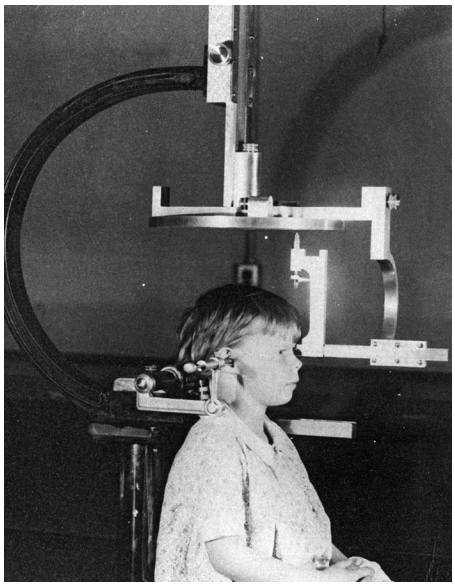
The introduction of the cephalometer by Holly Broadbent in 1931 was another important milestone that placed orthodontic research on a scientific foundation (Fig. 2-12).[157] For the first time, it made possible the accurate study of the facial bones in the growing child (Figures 2-13 and 2-14). It became a valuable supplement to the orthodontist's plaster models and intraoral x-rays. The value of serial cephalograms in clinical practice was quickly realized. Broadbent's original work on the "face of the normal child" and Brody's classic research "on the growth pattern of the human head from the third month to the eighth year of life" were among the earliest contributions.[163] These were followed by the research of Down's "Variations in Facial Relationships,"

• **Figure 2-12** Photograph of Holly Broadbent (1894-1977). *From Broadbent BH Sr., Broadbent BH Jr and Golden WH: Bolton Standards of Dentofacial Developmental Growth, St. Louis, C.V. Mosby, 1975.*



• **Figure 2-13** Broadbent was the first to develop the standardized lateral "head plate." The cephalometer is a device for holding the patient's head, the x-ray film, and the central ray of the x-ray machine in proper relationship with one another. Ear-rod extensions are necessary to adjust the head so that the profile is centered, regardless of the size or shape of the head. The orbital pointer and the ear rods adjust the patient's head along the horizontal or Frankfort plane. An adjustable chair is used, and the teeth are placed in "centric occlusion" unless otherwise indicated. The cephalometer may be rotated so that posterior and anterior radiographs as well as profile radiographs can be taken. The central ray is directed through the ear rods, thereby producing a circle on the x-ray film. *From Broadbent BH Sr., Broadbent BH Jr and Golden WH: Bolton Standards of Dentofacial Developmental Growth, St. Louis, C.V. Mosby, 1975.*

the work of Thompson in "Functional Analysis of Occlusion," Wylie's "Assessment of Anterior-Posterior Dysplasia," and the work of Margolis' "Basic Facial Pattern and Its Application in Clinical Orthodontics."[174] The use of cephalometric radiography in clinical practice became widespread



• **Figure 2-14** The cephalostat device, as described in Figure 2-13, is shown with a patient who is positioned and ready for film exposure. *From Broadbent BH Sr., Broadbent BH Jr and Golden WH: Bolton Standards of Dentofacial Developmental Growth, St. Louis, C.V. Mosby, 1975.*

after World War II and made clear to all clinicians that many of the Class II and Class III malocclusions being treated actually resulted from abnormal skeletal relationships rather than just malposed teeth.[165] These radiographic truths were hard to ignore and further inspired orthodontists and surgeons to search for operative solutions.[181]

Charles Tweed and Raymond Begg

Another "orthodontic truth" was also soon to fall. A purest "Angle" approach to maintaining and straightening all of the teeth in all patients frequently proved untenable with regard to the maintenance of the occlusion after the appliances were removed.[54,144,145] This non-extraction, arch-expansion approach gave little consideration to long-term periodontal health or to the individual's overall facial aesthetics.[161] The extraction of teeth (typically the bicuspids) to achieve occlusal stability and periodontal health was reintroduced into American orthodontics during the 1930s by Charles Tweed (Fig. 2-15) and simultaneously into the United Kingdom (Australia) by Raymond Begg (Fig. 2-16) (see Chapter 17 for in-depth discussion).[47-49,59,204]

Lawrence F. Andrews

Dr. Lawrence F. Andrews' pioneer contributions to the field of orthodontics and the treatment of dentofacial deformity must also be mentioned (Fig. 2-17).[2-4] After completing orthodontics training at Ohio State University in 1958, he entered private practice that was limited to orthodontics. Early in his career, Dr. Andrews recognized clinical problems that were yet unsolved and sought solutions. This sent him

on a search to better understand occlusion as well as deviations from normal. Between 1960 and 1964, Dr. Andrews began to gather data for analysis. One hundred and twenty non-orthodontic normal (dental) models were acquired with the cooperation of local dentists, orthodontists, and a major university. The models selected for study were of teeth that had never undergone orthodontic treatment; that were straight and pleasing in appearance; that had a bite that looked generally correct; and that, in Dr. Andrews' judgment, would not benefit from orthodontic treatment.

Dr. Andrews studied the crowns of this multisource collection of models to ascertain which characteristics, if any, would be found consistently in all of them. Angle's molar cusp groove concept was validated but found to be incomplete. After meticulous evaluation, including comparison with "treated cases" from the nation's most skilled orthodontists (n = 1150), six consistent occlusal characteristics were formulated by Dr. Andrews in general terms and then explained in detail.[2] The six fundamental qualities or *Six Keys of Optimal Occlusion* were validated not solely because all were present in each of the non-orthodontic normal models (n = 120) but because the lack of even one of the six was a defect that was predictive of an incomplete end result in the orthodontically treated models that were studied (n = 1150).

The significant characteristics (i.e., the *Six Keys of Optimal Occlusion*) described by Andrews that were found in all of the non-orthodontic normal models were as follows:

Key I: Interarch (molar) relationship
Key II: Crown angulation
Key III: Crown inclination
Key IV: Rotations
Key V: Tight contacts
Key VI: Curve of Spee

In his published article, Dr. Andrews acknowledged that, although each normal person is unique in his or her own way, they nevertheless have much in common.[2] The 120 non-orthodontic normal models studied differed with regard to certain aspects, but all shared the Six Keys. Dr. Andrews suggested that we use as our benchmark "nature's best" and that, in the absence of abnormalities outside of our control, we limit compromise and strive for the ideal. He developed the *straight-wire appliance* in 1970 for orthodontic use to help accomplish these objectives. This preadjusted appliance soon became the standard of the specialty.[2-4]

Dr. Andrews then went on to describe six fundamental principles that are necessary to achieve both facial and dental harmony: the *Six Elements of Orofacial Harmony*. Both of these aspects—facial and dental harmony—are frequently absent in the patient with dentofacial deformity. Dr. Andrews was one of the first orthodontist to clarify the importance of addressing both facial and dental harmony from the beginning of treatment to achieve the best facial form and head and neck function for each patient. Dr. Andrews stated that, for the maxillomandibular complex to be in harmony (i.e., to have all elements in alignment) with the overall face, the following must be present:

Element I: Proper arch shape and positioning of the maxillary and mandibular teeth (roots) over the basal bone
Element II: Proper horizontal (sagittal) projection of the maxilla
Element III: Proper width of the maxillary and mandibular arches
Element IV: Proper vertical height of the maxilla
Element V: Proper prominence (shape) of the chin (i.e., pogonion prominence)
Element VI: Establishment of the *Six Keys to Optimal Occlusion*

He studied each of these Six Elements and defined both qualitatively and quantitatively how the orthodontist and the surgeon can work together to achieve these objectives for each patient.

William R. Proffit

By the mid 1970s, Dr. Proffit recognized the benefits of a collaborative surgeon–orthodontist interaction for the correction of dentofacial deformities.[164] He and others convincingly demonstrated to surgeons that rectangular orthodontic arch wires in edgewise brackets were satisfactory for surgical patients without the need for the intraoperative placement of Erich arch bars. This paved the way for the routine preoperative orthodontic relief of dental compensations, and it was followed by the placement of orthodontic "surgical wires and hooks" for intraoperative use. After the initial surgical healing, a smooth transition to orthodontic maintenance and detailing soon became the standard of care. Dr. Proffit was also an early believer in the importance of a collaborative effort to understand the patient's presenting dysfunction and dysmorphology and then to develop a comprehensive treatment plan. The use of a cephalometric analysis with prediction tracings followed by dental model planning with splint construction became the routine. Dr. Proffit and others also insisted on analysis of the early results that were achieved. This was followed by critical studies of the long-term outcomes after various surgical approaches and orthodontic techniques were employed. This analytic approach has been responsible for much progress in the field over the past four decades.

According to Dr. William R. Proffit* (Fig. 2-18), orthodontics in the 21st century differs from that of the previous century in three fundamental ways[162,163]:

1. *There is more emphasis on both facial and dental aesthetics and less on the details of dental occlusion as an overriding objective.* This has much to do with the safe and reliable orthognathic surgical techniques that are currently

*Please note that the author of this text has paraphrased Dr. Proffit's original work.

• **Figure 2-18** Photograph of William R. Proffit (1936-Present)

available and with the recognition that long-term stable occlusion and periodontal health can best be achieved in conjunction with harmonious jaw relationships. This will require extractions when necessary to uncrowd and achieve periodontal health; decompensating orthodontic therapy to place teeth that are solidly in the alveolar bone; and jaw-straightening surgery, when indicated.

2. *Patients and families expect greater involvement in the treatment planning process*. Full disclosure requires the orthodontist to consider and review ideal and compromised treatment options. Providing a balanced and objective assessment of each option's effect on facial aesthetics, dental stability, periodontal health, speech articulation, and the upper airway is ideal. Consultation with appropriate dental, surgical, and medical specialists before instituting treatment has become the standard of care.
3. *Orthodontics is now offered not just to children, adolescents, and young adults but also to older adults through an interdisciplinary approach.* Consideration should be given to facial aesthetics, occlusion, periodontal health, the upper airway, speech articulation, and the long-term maintenance of the dentition. There is increased emphasis on coordinated treatment with other dentists, surgeons, and medical specialists. Taking advantage of currently available sophisticated orthodontics and orthognathic surgery to provide individuals of all ages with quality care should now be considered routine.

Early Pioneers in the Field of Orthognathic Surgery

Mandibular Setback for Prognathism

Simon Hullihen described a procedure for the correction of mandibular dentoalveolar protrusion in the *American Journal of Dental Science* in January 1849 (Fig. 2-19, *A*).[18,98] Technically, this was a bilateral bicuspid region wedge osteotomy to "set back" the anterior mandibular dentoalveolar segment. The osteotomy did not violate the inferior border of the mandible. The procedure was performed on a middle-aged woman whose mandibular deformity was the result of a severe burn scar contracture of the anterior neck and lip from an injury that had occurred during her childhood (see Fig. 2-19, *B* and *C*).

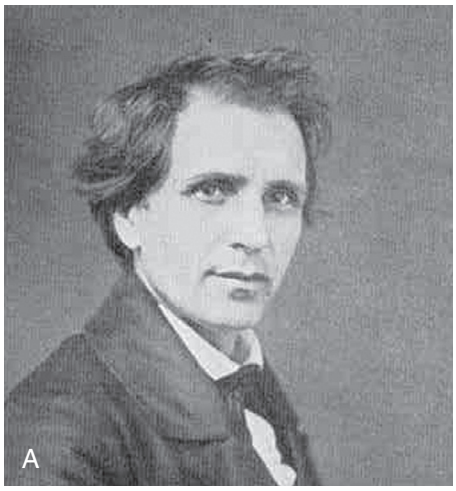
In 1887, Berger from Lyon, France, described bilateral condylar neck osteotomies to set back the prognathic mandible.[90] In 1895, Jaboulay also reported the bilateral osteotomy of the condylar neck (condylectomy) for the correction of prognathism.[100] This method continued to be popular in France for the treatment of prognathism through the 1950s.[75]

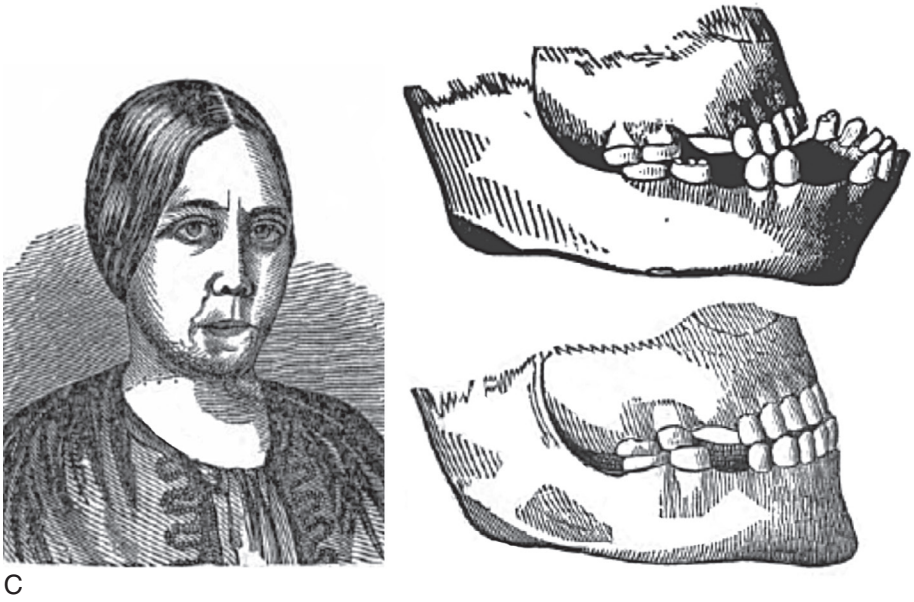
On December 19, 1897, Vilray Blair in St. Louis, Mo, carried out a distinct modification of the original Hullihen procedure for the treatment of mandibular prognathism (see the "Second Patient (Operation)" case report by Dr. Angle earlier in this chapter) (Fig. 2-20).[38] The operation was performed on a 22-year-old man with asymmetric mandibular prognathism. The young man had difficulty with chewing and speech articulation, and he also was self-conscious about his appearance; thus, he was enthusiastic about proceeding with the recommended surgical plan. Dr. Blair stated that the immediate surgical objective was to carry out bilateral body osteotomies to shorten the horizontal ramus [body of the mandible] and to change the mandibular angle [rotate the distal mandible counterclockwise], thereby allowing for the closure of the open bite. Dr. Blair's preoperative concerns about the operation included the following:

1. Could a portion of the mandible be cut out on each side in a satisfactory way?
2. Would sacrifice of the inferior dental nerve cause detrimental injury to the distal mandible?
3. After healing had occurred, would the mandible continue to grow and cause a recurrence of the deformity?

Through cadaver dissections, Dr. Blair satisfied his concerns regarding whether the mandible could be sectioned and repositioned successfully. As a result of the age of the patient (22 years), he had little concern regarding further growth after surgery. He conferred with two other surgeons (Dr. E.H. Gregory and Dr. P. Tupper), both of whom concurred that the surgical plan seemed reasonable. The patient was also under the care of Dr. J.W. Whipple (orthodontist). Dr. Blair had discussed the feasibility of a surgical solution for mandibular prognathism with Dr. Angle (the patient had also consulted with Dr. Angle before surgery), and Dr. Angle "had advised such an operation."[38]

The surgery was carried out at the Missouri Baptist Sanatorium. The surgery commenced with the patient under chloroform anesthesia at 9:20 AM with the patient in the recovery room by 10:30 AM. During the operation, the patient's head was hyperextended over the end of the operating room table. Skin incisions below the inferior border of the mandible on each side provided exposure. The incisions extended up into the mouth and involved cutting through





• **Figure 2-19 A,** Photograph of Simon Hullihen (1810-1897). **B,** Illustration of anterior mandibular dento-alveolar segmental osteotomy proposed and **C,** carried out by Dr. Hullihen. **A** *from Ambrecht EC: Hullihen, the oral surgeon.* Int J Orthod Oral Surg *23:377, 511, 598, 711, 1937.* **B** *and* **C** *from Hullihen S: Case of elongation of the under jaw and distortion of the face and neck, caused by a burn, successfully treated.* Am J Dent Sci *9:157, 1849.*

the mucous membrane. A full-thickness osteotomy was to be completed on the left side of the mandible between the first and second bicuspids and on the right side between the second bicuspid and the first molar. The osteotomy was initiated with a "double-bladed saw" three quarters of the way through on each side; the inferior border remained intact.[38] This allowed for the presence of a stable mandible on each side before the cut was fully completed on either side. A drill was used to place holes on either side of the osteotomy site for eventual "cooper wire fixation"[38] near the inferior border on each side before cutting through the inferior border on either side. After the completion of both full-thickness osteotomies, soft gutta-percha was placed over the mandibular dentition, and the upper and lower teeth were firmly wired together through the gutta-percha. This method of intermaxillary fixation immobilized the distal mandible in its new position for the closure of the open bite. Dr. Blair stated that "this method of fixation was suggested to him by seeing Dr. Angle's fracture bands."[38] The fracture band method of mandible fracture management was commonly in use.

Dr. Blair stated that, as the patient was emerging from the anesthesia, the vomiting of mucus and blood occurred, thereby necessitating the cutting of the intermaxillary fixation.[38] After the vomiting subsided, rather than reapplying intermaxillary fixation, a Barton bandage of plaster was used to secure the mandible into occlusion with the maxilla.[21] When the Barton bandage was removed several weeks later, Dr. Blair felt that there was "bony union on the right side and a very slight but perceptible motion on the left side when the fragments were grasped."[38] Dr. Blair decided to take the patient to the office of the treating dentist (orthodontist), Dr. Whipple. He requested that Dr. Whipple place two dental bands with a bar between them across the weak left osteotomy site. This would afford the patient sufficient support and allow him to go without the additional protection of a Barton bandage or intermaxillary fixation." Unfortunately, while he was tightening the bands across the left and right osteotomy sites, Dr. Whipple "broke the union of the provisional callus."[38] At this point, Dr. Whipple applied properly adjusted bands to the teeth on the left side of the mandible, and Dr. Blair reapplied a Barton plaster external facial bandage.[38] Dr. Whipple also placed crowns on the mandibular teeth posterior to the osteotomy sites so that the molars would occlude properly with the upper teeth, and he filled some points on the teeth to improve the occlusion of the incisors.[38] Apparently, the combination of the mandibular setback with the clockwise rotation resulted in "a small [osteotomy] gap between the second bicuspid and first molar on the right side" but "without a gap [previous edentulous space] in the left first bicuspid region."[38] Despite these difficulties, the osteotomies went on to heal with a reasonable correction of the occlusion.[38] Dr. Blair stated that there was "almost a complete loss of cutaneous sensation of the lower lip" but that the "sensation of the tooth-pulp is good."[38]

Interestingly, Dr. Whipple, the treating dentist and orthodontist, published his version of the patient's surgery, convalescence, and ultimate result in *Dental Cosmos* in 1897.[212] This was before the journal publication by Dr. Blair, in which he gave a full account of the case from his perspective.[38] Although Dr. Whipple's description of events varied somewhat from what was eventually reported by Dr. Blair, both concurred that the procedure had taken place and that it was a success.

In his textbook, Dr. Blair cautions the surgeon that "the lower jaw should be set back only far enough to be in harmony with the rest of the face" and that the surgeon should "leave it to the orthodontist to bring forward the upper incisors if necessary."[40] He stated that "an orthodontist should be involved in the planning of the patient's treatment from the beginning."[40] For some patients, Dr. Blair notes that "it would be of considerable advantage to have the upper jaw [orthodontically] expanded and the upper incisors and canines brought forward before the lower jaw is surgically set back."[40]

A horizontal osteotomy through the ascending ramus, on each side and above the occlusal plane, as a method of "setting back" the prognathic mandible was first described by Lane.[117] During the early 1900s, Blair[39] and Babcock[19] also made use of the horizontal ramus osteotomy on each side for the correction of prognathism.[36]

In 1912, Harsha reported bilateral wedge resections of the mandible body near the angle regions to set the mandible back; this was similar to the procedure that Blair described in 1897.[89] Unfortunately, at least one of his reported patients suffered the loss of (and the eventual need to remove) the entire anterior part of the jaw. In 1945, Moose[143] may have been the first to describe a fully intraoral technique to carry out horizontal ramus osteotomies for the correction of mandibular prognathism. In 1950, G.V. Barrow and Reed O. Dingman discussed the surgical management of mandibular prognathism.[22] They described a method to determine the exact amount and shape of mandibular bone to be resected on each side by using dental models that involved the construction of splints and templates. Their described meticulous approach was similar to that of Angle in the 1903 edition of his textbook.[7] The operation was reported by Dingman as having a two-stage approach[71,72]; this was to separate the intraoral and extraoral aspects to maintain control of the segments and to limit the risk of infection. During the first stage, the teeth to be extracted (i.e., the first molars) were removed with the use of local anesthesia. As determined by the "preconstructed template," osteotomies for wedge resection were initiated through the intraoral approach at the time of the extractions. Approximately 4 weeks later, the patient was anesthetized in the operating room for the second stage. An incision of the skin of the neck was made 2 cm below the inferior border, and the lower aspect of the mandible was exposed on each side. The previous intraoral vertical cuts on each side were identified. With a power-driven bur or saw, the two vertical cuts were continued through the inferior border. Attempts to preserve the inferior alveolar nerve were made. Stabilization across the osteotomy on each side site was with 24-gauge stainless-steel wires. The teeth were placed into occlusion with the use of either orthodontic appliances or Erich arch bars. In either case, to improve accuracy, the mandibular dentition was secured into a prefabricated acrylic wafer before intermaxillary fixation occurred.

In 1954, J.B. Caldwell and G.S. Letterman devised a vertical osteotomy of the ascending ramus that involved the decortication and perforation of the fragments and then the splitting of the medial and lateral cortices of the ramus to allow for setback of the mandible followed by direct wire fixation.[45,46] This innovative technique had the advantage of providing at least a degree of overlapping of the bone for more reliable and rapid healing.

All of these techniques for the management of mandibular prognathism[79,87,91-93,96,138,167,211] eventually fell by the wayside after the introduction by Hugo Obwegeser of what we now refer to as the "intraoral sagittal splitting of the mandibular ramus," which is described later in this chapter.[149] The stabilization of the osteotomy segments is now generally accomplished with titanium bicortical screws

or with a titanium plate and screws in accordance with the pioneering innovations of H. Luhr, who is also discussed in a later section of this chapter.[127]

Mandibular Advancement for Retrognathism

An important early maxillofacial textbook publication was *Surgery and Diseases of the Mouth and Jaws* by Vilray P. Blair (Fig. 2-21).[40] At the time of publication, Dr. Blair was a Major in charge of the subsection of Plastic and Oral Surgery, Section of Surgery of the Head Office of the Surgeon General of the Army in Washington, DC.[197] He was also a professor of oral surgery at the Washington University Dental School and an associate in surgery at the Washington University School of Medicine in St. Louis, Mo. In his textbook, Chapter 21 deals with the treatment of deformities and malrelations of the jaws.

Dr. Blair cautions that, before entering into jaw-straightening surgery, the surgeon would be well advised to do the following:

- To not undertake any cases without first having the fullest confidence in his or her patient
- To remember that procedures undertaken for only "moderate" deformity should not be taken lightly
- To remember that maximum restoration will also require orthodontics
- To remember that the earlier a competent and genial orthodontist is associated with the case, the better it will be for both the surgeon and the patient

In the 21st century, these remain useful words of wisdom for the surgeon to consider before entering into the treatment of a patient with a jaw deformity.

According to Dr. Blair, for the treatment of mandibular micrognathia, a surgical procedure may be used to "bring forward the lower jaw to harmonious outline" with the maxilla.[40] Malocclusion in a patient with a jaw deformity results from the "pressure and counter pressure of growth and apposition."[40] Normal occlusion cannot be established by jaw surgery alone. To reach certain objectives, the surgeon "shall have knowledge of occlusion and of the scope and limitations of orthodontic procedures."[40]

1920

• **Figure 2-21** Vilray P. Blair published a text entitled *Surgery and Diseases of the Mouth and Jaws,* the first edition of which was published by the C.V. Mosby Company in 1912.

Blair went on to say this: "We have to accept the upper jaw position but the lower jaw is capable of almost any kind of surgical adjustment. The complication of an ununited fracture of the lower jaw is rare. The complication of necrosis or loss of teeth from surgically sectioning the ramus is not reported in the world literature."[40] However, "osteotomy of the ramus of the mandible is a recognized procedure for the treatment of temporomandibular joint ankylosis."[40] Esmarck, who was a prominent surgeon when Dr. Blair was discussing this treatment, recommended the removal of a whole section of the horizontal ramus to avoid a union (i.e., reankylosis) when creating a pseudoarthrosis for the treatment of temporomandibular joint ankylosis. However, Blair felt that surgeons did not need to concern themselves with the possibility of necrosis or nonunion when "completing an osteotomy through the inferior alveolar neurovascular bundle."[40]

Blair felt that the surgeon could correct mandibular retrognathia by completing a ramus osteotomy on each side and then "bringing the distal mandible forward to meet a good occlusion with the maxillary arch."[40] Intermaxillary fixation could then be achieved with stainless steel wires and the use of soft cement in between the occluding teeth.[40] Fixation across the osteotomy site was felt to be unnecessary. The (horizontal) ramus osteotomy was made at or just above the mandibular occlusal plane with the use of a Gigli saw placed transcutaneously.[39] The osteotomy was cut through the inferior alveolar neurovascular bundle, which was not felt to be important either to the circulation of the mandible or as a cause of disability. The ramus osteotomies were later made blindly and transorally with a Gigli saw.[40]

According to Dr. Blair, "the operation presented three distinct problems: (1) the cutting of the bone [which is the easiest of the three]; (2) the placing of the jaw into its new position; and (3) holding it there [for the time required for healing]."[40] He used postoperative x-rays to show that the fragments of the ramus remained in contact at the posterior border of the osteotomy. "[A]s the distal mandible is brought forward," said Dr. Blair, "a gap is created anteriorly while the fragments remain in contact at the posterior border. For healing to occur, the bone gap must be filled with granulations. The resulting bone scar tends to contract [relapse] for months afterwards."[40] The maintenance of tight intermaxillary fixation was felt to be essential to maintain the new position. Blair used iron wire for its strength, lack of stretch, and pliability; it could also be twisted, unless it was damaged by sharp instruments.[40] He also used quick-setting cement between the occlusal surfaces of the molars to prevent the placement of postoperative forces on the anterior teeth, which could cause the patient significant pain.[40]

Dr. Blair also used this same operation involving horizontal ramus osteotomies for the treatment of ankylosis associated with severe mandibular retrusion; this operation was first carried out by Dr. Mudd with Dr. Angle assisting in 1897. Dr. Blair also suggests addressing the residual chin deformity by either "injecting paraffin into the chin or by inserting a piece of cartilage or rib."[40]

Most of the early reported attempts at horizontally advancing the retrognathic mandible focused on the mandibular body. Dr. Blair specifically addressed the problem of an anterior open bite by rotating the distal mandible counterclockwise after body osteotomies and ostectomies. He states that the "sectioning of the mandible on both sides in front of the first molars [as long as the molars are in occlusion] is the preferred procedure. The anterior mandible can then be moved into good occlusion with the upper teeth. In other cases, it is necessary to remove a V-shaped section of the bone on each side with extraction of the tooth [bicuspid]. The apex of the V-shaped ostectomy segment is at the lower border of the mandible and usually a tooth is extracted from the site of the section on each side. The bone is cut using a Gigli saw or a cross-cut Fisher bur."[40]

Dr. Blair goes on to state that "the deformity is in both jaws but the operation is limited to the lower jaw. It is best to restore the lower jaw to its proper form and then manage the residual open bite by bringing down the upper incisors with orthodontic appliances or by extending the upper teeth with porcelain crowns. Fixation is achieved with a prefabricated splint constructed on plaster dental models. This will prevent pulling down of the distal segment by the digastric and geniohyoid muscles."[40]

A variety of techniques were carried out by pioneering surgeons to address concerns regarding the maintenance of contact between the fragments to achieve bony union; soft-tissue coverage to limit infection; opposing muscle pull to limit relapse; and adequate fixation. In 1928, a "step osteotomy" of the body of the mandible was proposed by Von Eiselberg.[201] Also in 1928, Gadd reported a stepped procedure for the body of the mandible for the purpose of correcting asymmetric mandibular deficiency.[80] That same year, Limberg completed L-shaped sliding osteotomies of the mandibular body to improve bone-to-bone contact after advancement.[122,123] In 1931, Kostecka published his work with the Blair-type transcutaneous horizontal ramus osteotomies with the use of a Gigli saw (Fig. 2-22).[115] In 1936, Kazanjian performed mandibular "step" osteotomies anterior to the mental foramen with extension back into the body of the mandible to allow for advancement and fragment approximation (Fig. 2-23, *A* through *D*).[68,103-108] The constant problems encountered with all of these approaches involved maintaining sufficient bone-to-bone contact and achieving adequate fixation for a stable long-term result. The problems were finally solved through the pioneering work of Hugo Obwegeser (i.e., the intra-oral sagittal splitting of the ramus of the mandible) and Hans Luhr (i.e., plate and screw fixation across the osteotomy site), which is described later in this chapter. In 1960, Caldwell described vertical osteotomies of the ramus with interpositional iliac bone graft for the correction of micrognathia.[45] A C-osteotomy of the ramus was later described by Caldwell and colleagues, in 1968.[46] Although these osteotomies with interpositional grafting are occasionally used for the management of mandibular retrognathism, the Obwegeser sagittal split ramus osteotomy is generally preferred. Throughout the 18th and 19th centuries, many surgeons saw the need to mobilize the maxilla for better access either to remove an epipharyngeal tumor or for the correction of maxillary deformity.

Maxillary Osteotomies for Management of Dentofacial Deformity

In 1868, David Williams Cheever of Boston published a report of a Le Fort I osteotomy for the purpose of exposing and removing a large nasopharyngeal polyp (Fig. 2-24).[55,88] After completing the tumor resection, the maxilla was placed back in its original location. Cheever stated, "so far as I know, the operation including both superior maxillary bones—is novel."[55] "Nothing but the posterior attachments of the upper maxilla now prevented their depression and hinging on the pterygoid processes. The upper jaw was brought down so as to expose the tumor."[55] By the early 1900s, reports of series of patients undergoing maxillary osteotomies for the purpose of tumor resection were detailed in the literature.[37]

With reference to the treatment of dentofacial deformities, in 1921 in Berlin, Cohn-Stock was the first to report an elective maxillary osteotomy to establish a preferred occlusion.[56,214] He used a two-stage approach (a precaution against flap necrosis) when completing an anterior maxillary osteotomy. Martin Wassmund, the founder of the "German school" of maxillofacial surgery, is credited with developing the one-stage anterior maxillary osteotomy.[205-207] The Wassmund procedure was completed through limited palatal and labial incisions with subperiosteal tunneling. The tunneling

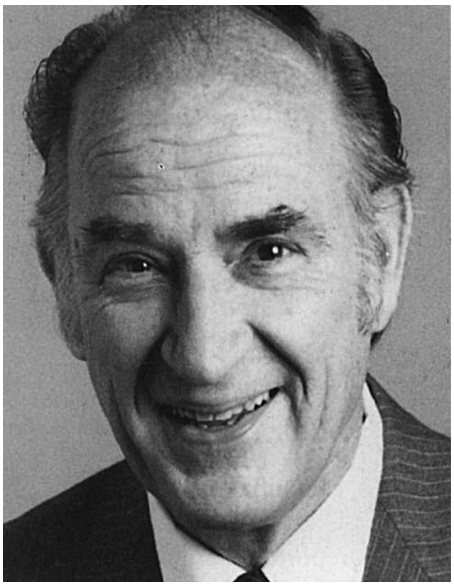
incisions limited mobilization, but this was thought to be necessary to maintain circulation. Karl Schuchardt is credited with developing the posterior maxillary segmental osteotomy.[171-173] This was completed with the use of broadly elevated full-thickness palatal flaps and limited labial flaps. In 1959, Köle described the combined simultaneous maxillary and mandibular anterior segmental (alveolar) osteotomies for the correction of bimaxillary protrusion and other forms of open bite, deep bite, and posterior crossbite.[111-114] He also pioneered the "corticotomy of maxillary and mandibular bones to facilitate the orthodontic movement of either a single tooth or group of teeth."[114]

Wassmund is credited with performing a first "total maxillary osteotomy" for the correction of a dentofacial deformity in 1927.[205-207] This was in a patient with an open-bite malocclusion. The maxillary osteotomy was completed through tunneling incisions without full down-fracture. Intermaxillary elastics were applied, with the gradual movement of the maxilla into occlusion occurring over the course of 2 weeks. In 1934, Axhausen was the first to mobilize and

• **Figure 2-25** Photograph of Hugo L. Obwegeser (1920-present).



• **Figure 2-26** Photograph of William H. Bell (1927-present).

immediately reposition a malunited maxillary fracture by Le Fort I osteotomy.[15-17] Pioneering surgeons described and continued to attempt maxilla osteotomies (anterior segmental, posterior segmental, and total maxillary) to improve the occlusion in individuals with dentofacial deformities.[44,50,57-59,61,116,119-121,126,141,158,160,169,180,183,212,213,219,220] Unfortunately, circulation requirements of the maxillary segments were poorly understood, mobilization was often incomplete, and available fixation options were limited.[66,86,87,110] These problems severely hampered the results that were possible for the patient with a jaw deformity.[142,217]

It was not until Hugo H. Obwegeser described the total horizontal Le Fort I osteotomy with complete down-fracture through a circumvestibular incision followed by full mobilization that the maxillary deformity could be universally addressed in all three planes, as described later in this chapter (Fig. 2-25).[153] Animal research carried out in William H. Bell's laboratory soon confirmed the vascular integrity of each specific dentoalveolar–musculomucosal mandibular and maxillary osteotomy-created flap that had been clinically described and used by Obwegeser and other European maxillofacial pioneers (Fig. 2-26).[29] Experimental confirmation of the adequacy of the circulation to each of these flaps, when properly elevated, encouraged the rapid dissemination of knowledge and the incorporation of orthognathic procedures into maxillofacial clinical practice throughout the world; this is discussed in more detail later in this chapter.

Dr. Hans Luhr's innovative ideas with regard to the development and clinical use of plate and screw fixation in maxillofacial surgery was the final piece of the puzzle, as described later in this chapter (Fig. 2-27).[127-134] Interestingly, the third edition of Dr. Blair's text, which was published in 1912, illustrates the use of what he calls "silver splints" for fixation across a mandibular osteotomy site (Fig. 2-28).[40] He stated that the use of these fixation devices was essential for healing. The "silver splints" look much like the titanium mini-plates with screws that we use today. He states that the "silver splints" were used on a patient for the correction of mandibular prognathism.

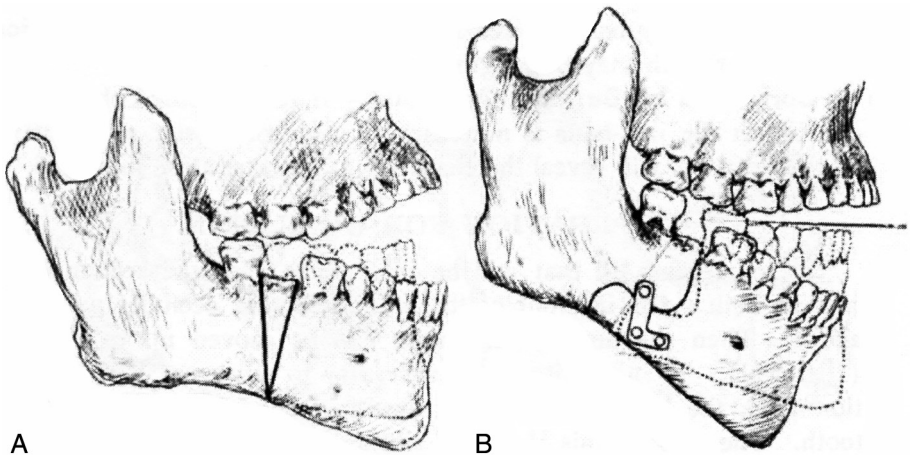
Hugo L. Obwegeser: Development of the Standard Orthognathic Procedures*

After completing his medical studies in mid 1945, Hugo Obwegeser started his career as an unpaid visiting doctor in a small hospital near his hometown. By doing so, he had

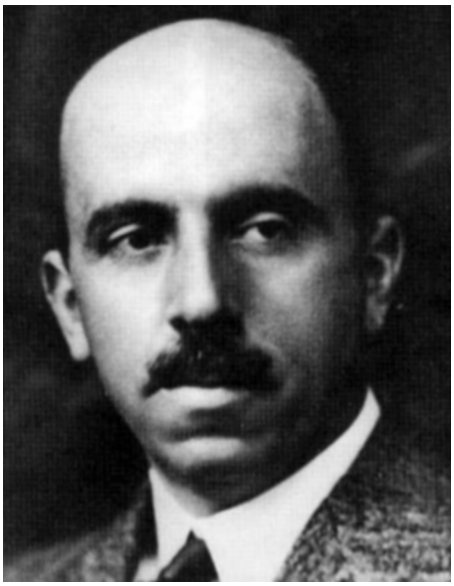
*Please note that this section was reviewed for accuracy by Dr. Obwegeser.



• **Figure 2-28 A,** Open bite of an extreme type in a young man showing how correction may be made by with V-shaped excision. This would have the disadvantage of shortening the jaw considerably, as shown in the reconstructed jaw, which is indicated by the dotted lines. **B,** A demonstration of how an operation involving an S-shaped bone cut that lengthens the jawbone provides for the better closure of the mouth. The silver splints at the site of the bone-cutter are absolutely necessary. *From Blair V:* Surgery and diseases of the mouth and jaws, *ed 3, St. Louis, 1917, C.V. Mosby Company, pp 309, Figures 287 and 288.*

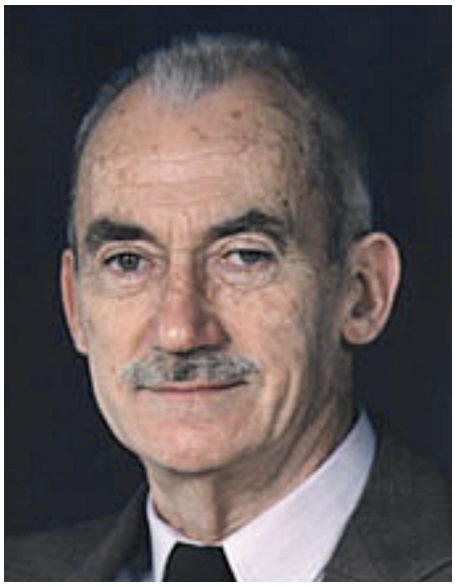
the opportunity to assist with surgery, including the treatment of extremity fractures. He did not know at that point in what direction his medical training would lead him. His uncle, an orthopedic surgeon, gave him this advice: "Whatever you want to become, a general medical practitioner in a small town or a specialist in any field of medicine, you will always need a fundamental knowledge of pathology and pathophysiology."[156] Obwegeser listened to his uncle, and, in October 1945, he accepted an unpaid position training under Professor Chiari at the Rockitansky Institute of Pathological Anatomy at the University of Vienna. At first, Obwegeser watched and listened, and he was occasionally allowed to assist at the dissecting tables. After 1 year of general surgery training and 2 years of pathology training, he was offered a paid position to train in maxillofacial surgery under Richard Trauner at Graz University. At Graz, Obwegeser would also train in dentistry and sit for the Austrian dental qualification examination (dentistry in Austria was a subspecialty of general medicine). Obwegeser trained and worked with R. Trauner for 6 years. He saw professor Trauner both as a teacher and like a father.[156] According to Obwegeser, Trauner "opened our eyes regarding the scope of the specialty [maxillofacial surgery] and stimulated us to see problems and find solutions for them."[156] The maxillofacial clinical practice at the Graz University Hospital included primary clefts, head and neck cancer, facial trauma, and the management of severe residual facial war injuries.

During that time and with a scholarship from the British Council, Trauner sent Obwegeser to Harold Gillies, the founder of modern plastic and reconstructive surgery (Fig. 2-29).[81-85] Obwegeser observed and worked with Gillies from October 1951 to February 1952, primarily on the reconstruction of war cases. From Dr. Gillies, Obwegeser



• **Figure 2-29** Photograph of Harold Gillies (1882-1960).

learned "how to plan the reconstruction of a facial defect and how to handle soft tissues."[156] Trauner also sent Obwegeser to spend time with Edward Schmid at Marien-Hospital in Stuttgart, where Obwegeser further advanced his knowledge of the handling of soft tissues, the movement of flaps to a new location, the management of cleft defects, and the closure of fistulas.[156] During his career, Obwegeser was also influenced by Dr. Paul Louis Tessier (Fig. 2-30).[184-196] Obwegeser states that, from Paul Tessier, he learned "the principal technique for advancing the whole middle third of the face and how to rotate the eye sockets into the planned position."[156] Tessier used these new techniques to



• **Figure 2-30** Photograph of Paul Louis Tessier (1917-2008).

correct posttraumatic or congenital anomalies of the upper half of the face. Tessier's "cranial approach to the orbits via the anterior base of the skull has created the possibility of producing a normal appearance and with that a normal life for many patients"[156]; this is described later in this chapter.

In June 1966, Dr. Obwegeser broadly introduced his orthognathic surgery techniques to North American surgeons when he presented a series of invited lectures and demonstrations at a comprehensive conference sponsored by the American Society of Oral Surgery at Walter Reed Military Hospital in Washington, DC.[156] At that time, Obwegeser also described other new ideas with broad implications for the scope of oral and maxillofacial surgery, including preprosthetic procedures, transoral approaches to the reduction of mandibular fractures, and the simultaneous resection and reconstruction of tumors of the mandible with the use of a transoral approach.[150-155]

According to Obwegeser, "With fundamental basic training in medicine and dentistry and through my teachers' influence, I was able to produce new ideas and procedures, assemble them in contrast to the then existing rules. The influence of my teachers enabled me to become a teacher myself. It enabled me from 1958 until 1987 to establish the so-called Zurich-School of Maxillofacial Surgery."[156]

The Transoral Sagittal Splitting of the Mandibular Ramus

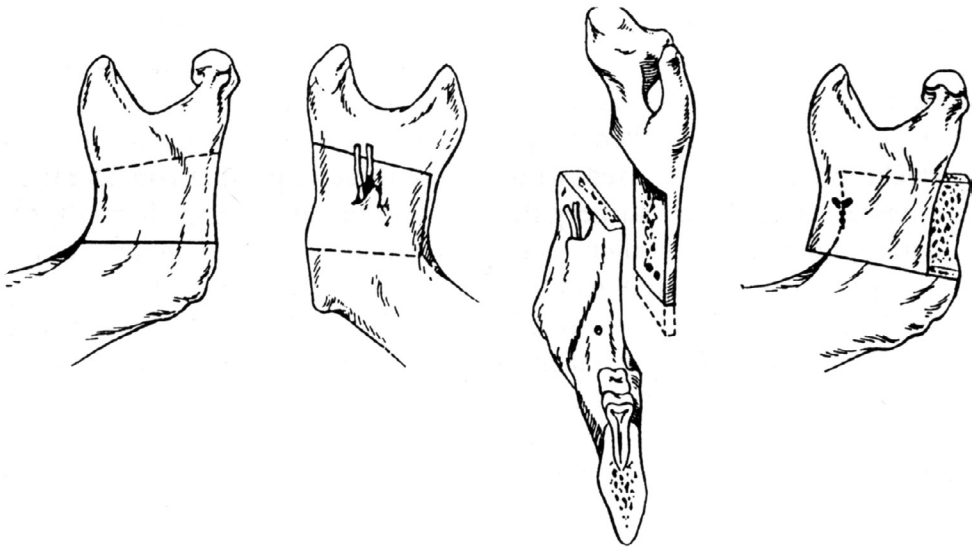
Trauner R, Obwegeser H: Zur operationstechnik bei der progenia und anderen unterkieferanomalien. **Dtsch Zahn Mund Kieferhlkd *23:11–25, 1955***

In 1947, Obwegeser started his training in maxillofacial surgery under the direction of Richard Trauner from the maxillofacial unit of the dental school at the University of Graz in Austria. At that time, orthognathic surgery was considered to be a series of unsatisfying procedures carried out primarily for the correction of prognathism. The available mandibular procedures were limited variations of horizontal ramus osteotomies. The basic techniques were those described by Blair[38-41] and Kostecka[115]:

> "The Blair-Kostecka technique included: The ascending ramus was cut on each side of the face [see Fig. 2-22]. The patient was placed in IMF [intermaxillary fixation] (6 to 8 weeks). It was estimated that approximately 50% of patients experienced significant complications including: partial or total relapse; residual malocclusion (open bite); pseudoarthrosis; injury to the facial nerve; injury to the inferior alveolar nerve; or parotid gland fistula. It was assumed that a primary reason for nonunion/malunion was the limited area of bone to bone contact across the osteotomy site once the distal mandible was placed in occlusion. This was compounded by contraction of the temporalis muscle of the non-fixed proximal segment causing further dislocation and separation. This complication was especially common when the procedure was used to correct mandibular deficiency as the distal mandible had to be advanced to achieve IMF [intermaxillary fixation]."[156]

In 1952, Dr. Obwegeser retrospectively reviewed a consecutive series (n = 36) of Dr. Trauner's mandibular osteotomies that had been treated with the Blair-Kostecka approach.[76,198-200] Obwegeser found a 50% incidence of significant complications. At his teacher's request to look for a better way to solve the mandibular deformity problem, Dr. Obwegeser made a personal decision about two aspects. First, he felt that the extraoral (cutaneous) approach left an unpredictable quality of scar and added a risk of injury to the inferior alveolar (sensory) nerve and the facial (motor) nerve, so he chose to find an intraoral approach. Second, he believed that the available techniques produced inadequate bone-to-bone contact to ensure stable bony healing. A new approach would have to provide broad contacting bone surfaces, even after anterior mandibular repositioning from micrognathia.

Dr. Obwegeser studied the cadaver mandible and concluded that "the ramus could be split along its sagittal plane—with a broad bony surface area for healing."[156] He had noticed a sagittal pattern on the radiographs of mandibular fractures that he had seen, and he wondered if such a fracture could be purposely created by a surgeon. Obwegeser was certain that "the inner and outer cortex could be cut at different levels and [then] the two corticotomies [could be] reconnected along the sagittal plane."[156] He was also convinced that the intraoral approach would not in itself result in infection. He had treated mandibular fractures via an intraoral approach by repositioning the fragments and providing intermaxillary fixation within 24 hours of the injury, and he had found that this resulted in minimal complications.[156]



• **Figure 2-31** Illustration demonstrating the first sagittal splitting of the rami. *From Trauner R, Obwegeser H: Zur operationstechnik bei der progenia und anderen unterkieferanomalien.* Dtsch Zahn Mund Kieferhlkd *23:11–25, 1955.*

Obwegeser then set out to sagittally split the ramus transorally on a cadaver. He did his cadaver work at the Institute of Anatomy in Graz, Austria (Fig. 2-31). Professor Trauner, who was Obwegeser's chief, then agreed to let Obwegeser try the new technique (i.e., intraoral approach sagittal split of the mandibular ramus) on a patient. Dr. Trauner would carry out his preferred approach (reverse L-shaped osteotomy of the ramus through a combined extraoral and intraoral approach) on one side, and Obwegeser would be allowed to try his technique on the other side. The procedure was carried out on an edentulous 27-year-old woman who presented with mandibular prognathism. A preoperatively constructed acrylic splint was made for the final occlusion, and the jaws would be wired together with the use of intermaxillary fixation (IMF). The procedure was carried out with the patient in a half-sitting position under local anesthesia on February 17, 1953. Unfortunately, when Obwegeser tried to execute his technique, the ramus "unexpectedly shattered instead of splitting."[156] The patient's mandible was set back, the occlusion was secured with the acrylic splint, and IMF was applied. Healing was satisfactory.

Two months later, a 24-year-old woman with mandibular prognathism and a nearly full dentition presented. Dr. Trauner again agreed to allow Dr. Obwegeser to try his technique. On April 22, 1953, with the patient in a half-sitting position and under local anesthesia, Dr. Obwegeser completed his osteotomy using long Lindemann burs, a keyhole saw and a fissure bur to perforate the cortex, and then a rose bur to connect the cortical perforations. An osteotome was finally used to split the ramus. The coronoid process fractured off, but, "with a gentile twisting maneuver, the cortical plates fell apart and the ramus was sagittally split."[198] On the other side, Dr. Trauner performed his inverted L-shaped osteotomy through a combined oral and extraoral approach. "This was followed by six weeks of IMF. The recovery was uneventful." The published result shows a favorable occlusion and good facial contour[198] (Fig. 2-32).

Obwegeser recognized that additional problems to be overcome included the need for special instrumentation, intraoral lighting, and improved anesthesia. He joined the Department of Maxillofacial Surgery at the University Hospital in 1954. In 1956, Dr. Hotz, an orthodontist, asked Dr. Obwegeser to perform the "sagittal splitting procedure" on one of his patients.[156] This patient was a 14½-year-old girl with a prognathic mandible who was partially maxillary edentulous.[156] On April 9, 1956, with the patient under nasotracheal intubation, Dr. Obwegeser successfully completed the sagittal splitting of the ramus of the mandible on each side. On one side, the lateral ramus broke off, but it was secured back in place at the end of the procedure with direct wires. The operation took 4 hours, and healing was uneventful. According to the surgeons, "She had a wonderful aesthetic and functional result—no external scars"[150] By the early 1960s, the sagittal splitting technique of the ramus of the mandible became routine for Dr. Obwegeser, and word soon spread worldwide.

Obwegeser mentions two important modifications to the sagittal splitting of the ramus of the mandible that later came about.[151-153] The first modification was in "the placement of the lateral corticotomy to increase the surface area of the bony contact for improved union and to accommodate a wider range of advancement of the distal mandible."[156] The change was from a horizontal orientation of the lateral corticotomy of the ramus to a vertical orientation of the lateral corticotomy of the mandibular body. In 1957, while an observer of Dr. Obwegeser in Zurich, Dr. Dal Pont "conceived the idea of changing the lateral corticotomy from horizontal in the ramus to vertical in the body."[156] Dal Pont assisted Obwegeser with this goal, and it worked. In

• **Figure 2-32** The patient shown underwent the first successful transoral sagittal split of the ramus on the left side. This operation was completed by Obwegeser. A transcutaneous inverted L osteotomy on the right side was completed by Trauner on April 22, 1953. **A,** Left profile views before surgery as well as 5 months and 22 years after the surgery. **B,** The patient's occlusion before and after surgery is also shown. **C,** The posteroanterior cephalometric radiograph shows the wire fixation on the inverted L side (the right side) and without wire fixation on the sagittal split side (the left side). *From Obwegeser HL: Orthognathic surgery and a tale of how three procedures came to be: a letter to the next generations of surgeons.* Clin Plastic Surg *34:335, 2007, Figure 4.*

1958, Dal Pont went back to his home base in Italy and eventually published these results himself.[62,63] However, Dal Pont failed to mention that the patient described was Dr. Obwegeser's patient. A second modification was also suggested by Dal Pont when he observed that, in some patients, the split did not go back all the way to the posterior border when the ramus was sectioned; satisfactory results nevertheless occurred.[64] This second modification was also recommended by Hunsuck and Epker when they "advocated that the osteotomy of the lingual side should be incomplete, extending just past the entrance of the neurovascular bundle."[156] This would result in an incomplete fracture along the medial aspect of the ramus.[65,67,77,78,99,136]

The Transoral Sliding Osseous Genioplasty

Trauner R, Obwegeser H: The surgical correction of mandibular prognathism and retrognathia with consideration of genioplasty. I. Surgical procedures to correct mandibular prognathism and reshaping of the chin. **Oral Surg Oral Med Oral Pathol *10:677–689, 1957***

Through the late 1950s, the correction of microgenia was achieved through onlay techniques to augment the deficient chin.[13,14,102,140] The procedures were carried out through a submental (skin) incision. Autogenous bone and cartilage grafts (e.g., rib, hip) and a variety of alloplastic materials (e.g., acrylic, Silastic, metal) were used to augment the deficient chin. The onlay bone grafts resorbed over time. The cartilage grafts healed in a capsule and were often mobile and displaced, thereby causing asymmetry. The alloplastic materials, although easy to fabricate and place, had a high complication rate that included infection, displacement, the erosion of underlying bone, the resorption of the dental roots, and an unfavorable appearance.

Early in his career, Dr. Obwegeser had the intention of finding a reconstructive technique that would correct microgenia through an intraoral approach, that would allow for sufficient bone contact for reliable union, and that would maintain the advancement without resorption or relapse. After evaluating a woman with a retrusive chin and normal occlusion and reviewing her lateral cephalometric radiograph, Obwegeser realized that a favorable chin contour could best be accomplished by sectioning the chin transversely (i.e., below the roots of the teeth and the mental foramen) and then advancing it. He used the same transoral incision that he was familiar with from mandibular fracture management. He used a Lindemann bur to make a horizontal osteotomy below the roots of the teeth and the mental foramen, and he then completed the osteotomy with a chisel. He repositioned the distal chin horizontally forward by 10 mm while maintaining the geniohyoid muscle pedicle. He fixed the chin in its new position with circummandibular threads around the chin and bicuspid regions. The threads were primarily secured over a prefabricated acrylic wafer that was placed on the occlusal surfaces of the mandibular teeth to prevent "cheese wiring" through the interproximal regions. Obwegeser published this successful chin osteotomy outcome in 1957 (Fig. 2-33).[150] Interestingly, an earlier publication by Hofer reported the sliding the inferior border of the chin forward.[94,95] Although this osteotomy was similar to the one reported by Obwegeser, it was completed through an extraoral incision, and it was performed on a cadaver rather than a living patient. Over the decades, few useful clinical modifications of the original chin osteotomy (i.e., the Obwegeser technique) have been found in the literature. They include a double-step advancement and the splitting of the osteotomy in the midline to control width and angulation.[150]

The Le Fort I (Type) Osteotomy

Obwegeser H: Der offene biss in chirurgischer sicht. **Schweiz Monatschr Zahnhlkd *74;668–687, 1964***

Early on during his career, Dr. Obwegeser recognized the necessity of developing a technique that would allow for the reliable repositioning of the maxilla. He realized that, for many jaw deformities, the occlusion could be restored with a mandibular setback, but a flat appearance to the midface and the stigma of the underlying condition would remain. Obwegeser explained that, by the 1950s, he realized solving this problem would require 1) safe surgical sectioning of the maxilla; 2) the ability to three-dimensionally reposition the maxilla in the operating room; 3) the ability to maintain

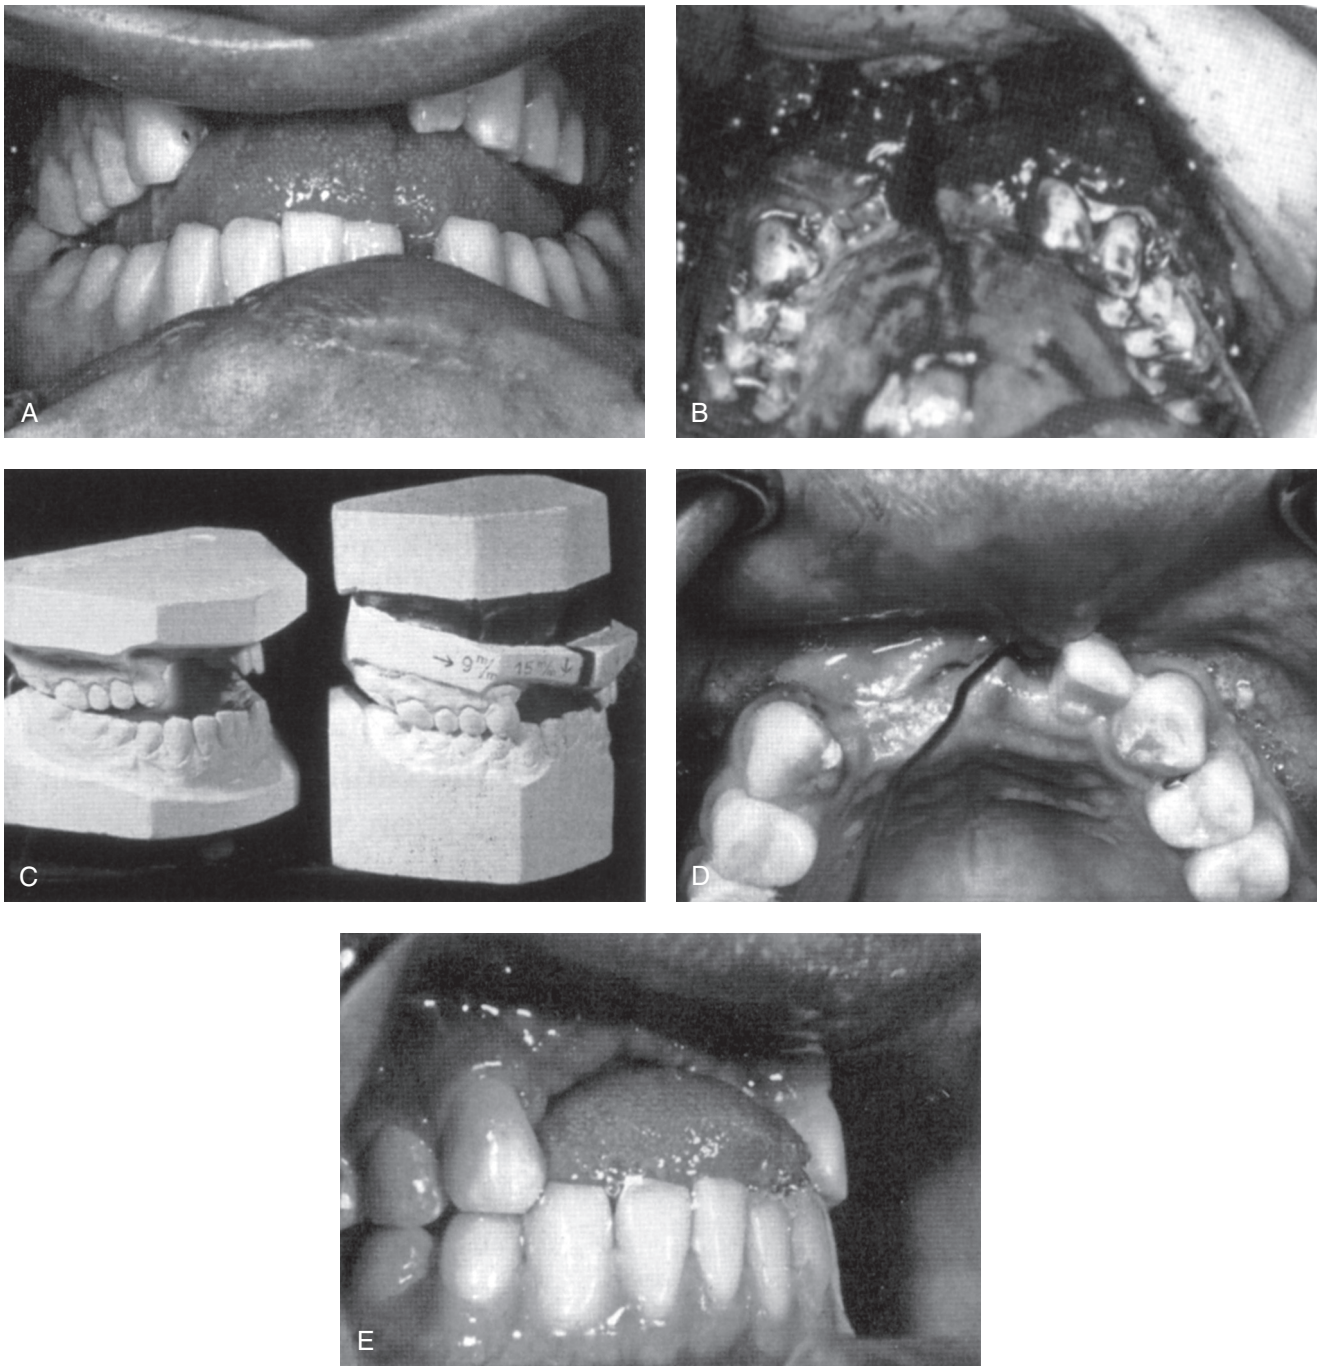
the upper jaw in the new position during healing, with 4) an acceptable complication rate and 5) a predictable outcome.

Obwegeser knew that Langenbeck[118] and Cheever[55] were able to section the maxilla horizontally above the roots of the teeth through skin incisions of the cheek and lip for the purpose of gaining access to the posterior pharynx and the skull base. Wassmund reported that, in 1927, he had "detached the maxilla as a Guerin-type fracture" (personal communication) but without separating it from the pterygoid processes.[205-207] He then used elastics (rather than a complete mobilization of the maxilla) to close the anterior open-bite malocclusion. Axhausen successfully completed osteotomies and repositioned the upper jaw in posttraumatic and cleft patients.[15-17] He used elastics to relocate the maxilla after an osteotomy of the upper jaw, which included separation from the pterygoid processes but without complete intraoperative mobilization. In 1942, Schuchardt reported about a posttraumatic midface deformity caused by a war injury in which he completed a horizontal osteotomy of the maxilla above the roots of the teeth as a first procedure.[171-173] Several weeks later, during a second operation, he fractured the pterygoid processes. After the second procedure, he used weight traction to horizontally advance the maxilla. He stated that "this procedure would have a large indication in cleft cases, but it would probably never come into use."[171-173] In 1951 and 1952, Obwegeser observed Sir Harold Gillies completing maxillary osteotomies to correct cleft maxillary deformities in numerous patients.[156] Dr. Gillies "used horizontal vestibular incisions to approach the maxilla," "but he only rotated the collapsed cleft segments with a Green-stick fracture at the pterygoid-maxillary junction."[156] This is similar to what Schmid reported in 1956 for the correction of posterior crossbites.[170] According to Obwegeser, neither Gillies nor Schmid completed the horizontal maxillary osteotomies with the purpose of advancing the maxilla.[156] Gillies and Rowe[84] and Gillies[85] did report that, in 1947, they had completed an osteotomy of the maxilla and were able to bring the upper jaw into the desired position in a patient with a cleft palate, with Gillies reopening the alveolar/palatal cleft and dividing the maxilla in two. This was followed by immobilization that lasted for 12 weeks. Gillies would secure the maxilla in its new location with the use of cast cap splints over the teeth that then attached to a vertical bar in front of the face and to a head cap. Gillies placed cancellous bone grafts on the steps (gaps) in the canine fossa regions and directly into the maxillary sinuses. Because of Gillies' reticence to advance the maxilla, the horizontal discrepancy in the jaws had to be overcome by setting the mandible back. Unfortunately, the patients retained their "dish face" with, at best, a "flat appearance."[156]

Throughout the 1950s, Obwegeser looked for solutions to correct the midface deformity seen in cleft and posttraumatic patients.[137,159] He believed that vertical vestibular incisions—which were felt by most surgeons of the day to be necessary to maintain the maxillary blood supply—limited successful outcomes.[156] He was convinced that the limited vertical vestibular mucosal incisions 1) prevented the full mobilization of the maxilla; 2) prevented the relaxed repositioning of the upper jaw in the operating room; and 3) prevented the placement of fixation and bone grafts, 4) thus further limiting the stability of the advancement and resulting in eventual relapse.

Obwegeser was able to innovate by making a quantum leap in the reconstructive possibilities of maxillary osteotomies for the correction of jaw deformities. In 1964, he was asked to treat an 18-year-old man who had been in a car accident 6 weeks earlier. The young man had sustained a fracture of the maxilla in two segments (palatal split), with telescoping occurring into the nose and the maxillary sinus. This resulted in a retropositioned maxilla with a severe anterior open bite. Three maxillary incisors were lost, there were multiple oronasal fistulas, and the vestibular mucosa had been lacerated circumferentially. There was initial healing of the soft tissues present, with scarring and malunion of the bones. To repair the deformity, Obwegeser realized that limited vertical vestibular incisions, which were part of his usual approach, were not feasible. He instead elected to reopen the circumferential vestibular incisions, also through the oronasal fistula opening (Fig. 2-34). He then completed a Le Fort I osteotomy through the two halves of the maxilla that had healed in malunion. This required horizontal osteotomies above the teeth from the canine fossa past the tuberosities and through the sinus on each side. He used osteotomies and a fissure-type bur on a rotary drill to complete the osteotomies. He raised the nasal mucosa, detached the septum, cut through the lateral nasal walls, and separated the pterygoid plates vertically. With each step, he confirmed that the vascularity to the dentoosseous–musculomucosal flap was not jeopardized. With finger pressure, the maxilla was disimpacted via the down-fracture technique. Obwegeser fully mobilized the maxilla to move it forward. He recreated the palatal fracture (segmentation) to independently reposition the two halves of the maxilla. He realized that the descending palatine arteries were no longer intact; while working through a circumvestibular incision, he was able to split the maxilla into two segments and to maintain the circulation to each half. He simultaneously closed the oronasal fistulas, fixed the maxillary segments in place, and established the preferred occlusion. By doing so, it was not necessary to complete mandibular osteotomies to correct the occlusion.

Over the next several years, Obwegeser succeeded in advancing the maxilla in cleft patients "without the need to establish the occlusion with a mandibular setback as in years past."[156] On April 14, 1968, he treated a patient with unilateral cleft lip and palate and a severe maxillary deficiency. Obwegeser advanced the lesser segment by 15 mm and the greater segment by 13 mm. The Le Fort I osteotomy was completed, and this was followed by down-fracture and mobilization. He recognized that "mobilization—release of scar tissue—and having both segments absolutely loose—was the entire key to success." He realized that he could



• **Figure 2-34** The first case of the advancement of the maxilla in two segments through a circumvestibular approach was performed by Obwegeser in 1964 to correct a posttraumatic deformity. **A,** A severe anterior open bite caused by posttraumatic telescoping retromaxillism in two segments. **B,** Oral-nasal communication and vestibular scarring on both sides. **C,** Model surgery indicating 9 mm of advancement and 15 mm of movement vertically down. **D,** Palatal view after reconstruction. **E,** The final occlusion after the complete mobilization of the two halves of the maxilla. *From Obwegeser HL: Orthognathic surgery and a tale of how three procedures came to be: a letter to the next generations of surgeons.* Clin Plastic Surg *34:341, 2007, Figure 10.*

advance the maxilla as far forward as he needed to because he had a blood supply that was, surprisingly, still satisfactory.[156] He then used blocks of cancellous bone from the iliac crest to fill the horizontal and vertical gaps.[156]

On September 5, 1969, Obwegeser completed the first simultaneous sagittal splitting of the ramus of the mandible and a Le Fort I osteotomy on a patient. He realized that he could establish the occlusion with either procedure and that he needed to vertically lengthen the mandible while at the same time setting it back. Thus, "both jaws had to be moved to improve the aesthetic result."[156] He used his clinical aesthetic judgment in combination with a review of a

cephalometric radiograph to confirm what needed to be done. With the maxilla and the mandible completely freed up, he placed them into occlusion as a single unit. He then repositioned the maxillomandibular complex "according to [his] imagination."[156] When he was satisfied with the aesthetic result, he fixed the maxilla and then the mandible in place with wires and bone grafts. He maintained the patient in IMF for 6 weeks, after which he reported, "The occlusal and facial aesthetic results were excellent!"[154]

Only minor modifications have been introduced to the basic Obwegeser design of the maxillary Le Fort I osteotomy. According to Dr. Obwegeser, "In time, internal fixation with plates and screws became a reality. In 1968, Hans Luhr published his [initial] work with plate and screw fixation. It revolutionized internal fixation, limiting the need for extended IMF and increased [the osteotomy] stability."[156]

William H. Bell: Experimental Studies to Confirm the Biologic Basis of the Standard Orthognathic Procedures*

William H. Bell attended a Jesuit high school, college, and dental school in St. Louis, Mo (Fig. 2-26), and he would be forever affected and influenced by the Jesuit challenge to "be men for others." After completing dental school in 1954, he interned in oral surgery in New York City at the Metropolitan City Hospital. He recalls that "in any given week, [he] would literally see hundreds of patients who [were] candidates for either orthognathic surgery or orthodontics. Unfortunately, none of them received any treatment."[156] In 1955, he served as resident in oral surgery at the Jefferson Davis Hospital in Houston, Tex. Dr. Edward C. Hinds was the program director, and, at the time, it was considered one of the country's finest programs in reconstructive mandibular surgery. Hinds had refined and clinically applied the extraoral vertical ramus osteotomy technique for the correction of mandibular prognathism. The program was also strong in the management of facial trauma, particularly mandibular and midface fractures. In 1956, Dr. Bell was the first teaching fellow in oral surgery at M.D. Anderson Hospital in Houston, Tex. His clinical work was limited to extracting teeth and the treatment of benign tumors and cysts of the jaws, but he had the opportunity to observe innovative head and neck cancer surgery. According to Dr. Bell, "Dr. Hinds and the other American oral surgeons in Houston were aware of descriptions of both anterior and posterior maxillary osteotomies, but none were performed for orthognathic problems at that time"(personal communication). Bell envisioned the potential of maxillary osteotomies for the correction of dentofacial and posttraumatic deformities. He searched the English literature available to him for relevant studies, but he found none that supported the biologic foundation of these procedures. Dr. Sumpter Arnim encouraged Bell's interest in studying the circulation requirements of jaw osteotomies and offered experimental rabbits for use. After visiting the laboratories of orthopedic surgeons Drs. Rhinelander and Baraquay in Cleveland, Ohio, Dr. Bell performed a preliminary pilot study in rabbits to work out the details of microangiographic and histologic laboratory techniques (personal communication). This initial work gave support to these techniques for studying the biologic basis for jaw osteotomies. While at the University of Texas Dental Branch of the Texas Medical Center in Houston, Tex, and with support from U.S. Public Health Service grants, Dr. Bell carried out the first of his many revascularization bone-healing studies after completing maxillary and mandibular osteotomies with the use of adult rhesus monkeys, mongrel dogs, and baboons. In his first revascularization publication, Dr. Bell states the following: "Despite numerous clinical successes and occasional failures, the rationale for using various surgical techniques [for maxillary and mandibular osteotomies] remains virtually empiric. Basic questions concerned with the healing of the surgical wound produced by maxillary osteotomies and the vessels necessary to maintain blood supply to the bone segments and viability of the teeth have not been investigated."[24] Nine further animal laboratory studies would eventually be completed from 1969 to 1995, and these would validate the circulatory integrity of all of the basic osteotomies used in orthognathic surgery.[25-35]

In 1971, Dr. Bell was recruited by Dr. Robert Walker to the University of Texas Southwestern Medical Center in Dallas, Tex, to develop a research laboratory that focused on the vascularity and wound healing associated with maxillary and mandibular osteotomies (Fig. 2-35). This provided the opportunity to continue animal studies and to apply the knowledge gained in the laboratory to the solving of clinical challenges. For the next 20 years, he worked with and

trained 27 oral and maxillofacial surgery residents in his research laboratory at the University of Texas Southwestern Medical School. He also conducted weekly dentofacial deformity conferences for surgical residents, faculty, and visitors from every corner of the world as well as for Dallas community orthodontists and surgeons. Beginning in 1973 and continuing through 1985, Dr. Bell, Dr. Raymond White, and Dr. William Proffit wrote and edited the text *Surgical Correction of Dentofacial Deformities* (Fig. 2-36). Volumes I and II of this text, which were published in 1980, became the comprehensive clinical reference for the interdisciplinary art and science of the correction of dentofacial deformities by surgeons and orthodontists. This work combined an atlas of surgical and orthodontic procedures with sound diagnostic and biologic guidelines for their application. The outstanding supporting original artwork by Bill Winn was remarkable for its clarity regarding the presenting dysmorphic maxillofacial anatomy and for its demonstration of how surgical procedures can be used to solve clinical problems.

Biologic Basis for the Maxillary Anterior Segmental Osteotomy

Bell WH: Revascularization and bone healing after anterior maxillary osteotomy: a study using adult rhesus monkeys.* J Oral Surg *27:249–255, 1969

An investigation was designed by Bell and colleagues to delineate the biology of anterior maxillary osteotomy wound healing. This was done by studying revascularization and bone regeneration in monkeys with the use of microangiographic and histologic techniques after completing an anterior maxillary osteotomy. Standard anterior maxillary osteotomies (i.e., labial versus palatal pedicle) were completed with the Wassmund technique, and the animals were sacrificed at 1, 3, and 6 weeks after surgery. Before sacrifice, the common carotid arteries were exposed, cannulated, heparinized, and perfused with a suspension of Micropaque injection medium. Each maxilla was then dissected from the specimen, and radiographs were taken. The 1-week specimens confirmed a "blood clot in the center of the osteotomized fragments bounded by proliferating young granulation tissue."[24] The 3-week specimens "showed early callus formation between the bone fragments. Considerable subperiosteal new bone formation was present in some of the sections."[24] The 6-week specimens "showed osseous union of the osteotomized bone fragments with no evidence of necrosis."[24] According to Dr. Bell, "The results indicated that no single blood vessel, such as the incisive canal or greater palatine arteries, is essential to maintenance of circulation to the anterior maxillary fragment. Interosseous and soft tissue collateral circulation and the freely anastomosing gingival, palatal, floor of the nose and periodontal plexuses permit many variations of the anterior maxillary osteotomy technique [labial versus palatal pedicles] without detriment to the integrity of the blood supply to the anterior maxillary segment"[24] (Fig. 2-37).

Biologic Basis for the Anterior Mandibular Segmental Osteotomy

Bell WH, Levy BM: Revascularization and bone healing after anterior mandibular osteotomy.* J Oral Surg *28:196–203, 1970

In 1970, Bell and Levy published an experimental animal study to analyze the biologic basis for wound healing and revascularization after anterior mandibular segmental

osteotomy in adult rhesus monkeys (n = 11). Half of the experimental animals underwent a one-stage anterior mandibular segmental osteotomy that involved six teeth. The procedure was performed through a circumgingival degloving labial flap. The lingual soft-tissue pedicle remained attached to the osteotomized segment. Second bicuspids were extracted, and the mandibular anterior segment was set back. The second group underwent the same one-stage anterior mandibular segmental osteotomy, but this was performed through a labial vestibular incision with the maintenance of a gingival cuff around the labial aspect of the teeth. The lingual soft-tissue pedicle also remained attached to the osteotomized segment. The repositioned (set-back) anterior mandibular segment was stabilized with a prefabricated acrylic splint that was ligated to the teeth with interdental wires. The animals were sacrificed at specific postoperative intervals at weeks 1, 3, 6, and 24. Microangiograms and histologic slides were reviewed. The analysis of the data demonstrated that intraosseous and intrapulpal circulation to the anterior mandibular segments was maintained with the use of both of the surgical flap designs. The dento-osseous–musculomucosal flaps healed by osseous union within 6 weeks. In the control animals—in which the complete degloving of the labial and lingual soft tissues from the bone occurred—intraosseous necrosis, vascular ischemia, and nonunion resulted (Fig. 2-38).

Biologic Basis for the Posterior Maxillary Segmental Osteotomy

Bell WH, Levy BM: Revascularization and bone healing after posterior maxillary osteotomy. **J Oral Surg *29(5):313–320, 1971***

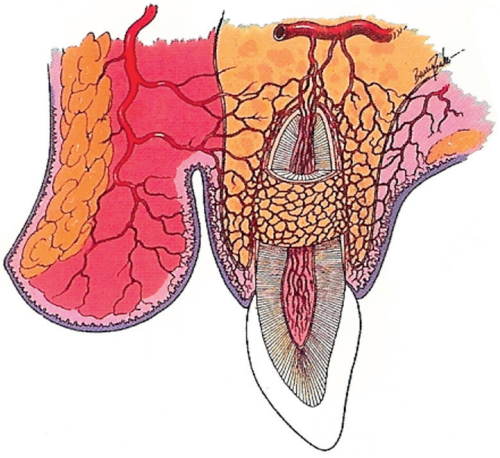
An animal model investigation was designed by Bell and Levy to clarify the biology of wound healing after posterior maxillary osteotomies with the Schuchardt technique (Fig. 2-39). In half of the posterior maxillary osteotomy flaps, the greater palatine vessel was ligated. The microangiographic and histologic studies were completed. At 1 week after surgery, the dento-alveolar segments remained freely movable. By 3 weeks, mobility had greatly diminished. After 6 weeks, the clinical union of the osteotomy segments

was seen. The individual teeth and the mobilized bone segments remained stable. There was minimal osteonecrosis and only transient vascular ischemia, and osseous union between most of the osteotomized segments occurred. No difference was seen with or without the ligation of the palatine vessels. The results of the experimental study suggested that "clinically analogous single-stage posterior maxillary osteotomies are biologically sound."[26]

Revascularization and Bone Healing after Maxillary Corticotomies

Bell WH, Levy BM: Revascularization and bone healing after maxillary corticotomies.* J Oral Surg *30:640–648, 1972

In 1972, Bell and colleagues published an experimental animal study to analyze the biologic basis for revascularization and bone healing after maxillary interdental corticotomies with the use of the Köle technique (Fig. 2-40). Five adult rhesus monkeys underwent Köle type procedures and analysis. One-stage maxillary corticotomies were performed bilaterally in the premolar and incisor regions in four monkeys; one monkey served as a control. Corticotomies were completed in each dento-osseous segment. These segments were then mobilized by a chisel between the corticotomy sites, and the wounds were closed. The mobile segments were stabilized with a preoperatively made acrylic splint by ligating each tooth to the splint with interdental wires. The experimental monkeys were sacrificed at 1, 7, 21, and 63 days after surgery. Microangiographic and histologic slides were reviewed. The procedures that were carried out were found to have a destructive effect on the maxillary incisors. The intraosseous and interpulpal circulation also appeared to be imperiled.



• **Figure 2-40** Illustration of blood supply to the anterior maxilla. The vascular architecture—which consists of freely anastomosing gingival plexus, palatal plexus, periodontal plexus, labial artery, intra-alveolar vessels, apical vessels, and pulp vessels—permits anterior maxillary osteotomies to be performed without compromising circulation to the anterior maxilla and the teeth. *Courtesy William Bell.*

Biologic Basis for the Le Fort I (Down-Fracture) Osteotomy

Bell WH, Fonseca RJ, Kenneky JW, Levy BM: Bone healing and revascularization after total maxillary osteotomy.* J Oral Surg *33:253–260, 1975

In 1975, Bell and colleagues published an experimental animal study that confirmed the biologic basis for bone healing and revascularization after total maxillary (Le Fort I) osteotomy carried out through a circumvestibular incision followed by down-fracture and disimpaction via the Obwegeser technique. Twelve adult rhesus monkeys underwent single-stage total maxillary osteotomy according to Obwegeser's protocol (Fig. 2-41). Two non-operated animals served as controls. In seven animals, the greater palatine arteries were preserved; in three animals, they were transected. The animals were sacrificed at the following intervals: immediately; after 2 days; and 1, 2, 4, 6, and 12 weeks after surgery. In all of the animals, the wounds healed without signs of infection or dehiscence. Revascularization and bone healing were studied with the use of microangiographic and histologic techniques (Fig. 2-42). Within 1 week after surgery, there was increased filling of both the endosteal and periosteal vascular beds. By 4 weeks, a callus that was composed of fibrous connective tissue and young bone was seen histologically. By 6 weeks, the callus contained mature bone. The 12-week specimen showed complete osseous bridging between fragments. Interestingly, the ligation of both greater palatine arteries had only minimal short-term effects on the perfusion of Micropaque through the intraosseous, intrapulpal, or soft tissues.

Biologic Basis for the Vertical Oblique Osteotomy of the Mandible

Bell WH, Kennedy JW, 3rd: Biological basis for vertical ramus osteotomies—a study of bone healing and revascularization in adult rhesus monkeys.* J Oral Surg *34:215–225, 1976

In 1976, Bell and Kennedy completed a microangiographic and histologic study of adult rhesus monkeys (n = 15) to evaluate the biologic basis for the vertical ramus osteotomies that were commonly in clinical use. Bone healing and revascularization of the proximal condylar segment were studied after pedicled and nonpedicled vertical ramus osteotomies were completed. The animals were sacrificed at specific postoperative intervals (1, 2, 3, 6, and 12 weeks), and microangiograms and histologic slides were reviewed. Specimens for which the proximal segment was not pedicled to soft tissue showed intraosseous necrosis, vascular ischemia, and delayed healing. Early osseous union, minimal osteonecrosis, and minimal vascular ischemia were found in pedicled specimens. The study confirmed that the circulation and viability of the proximal condylar segment was maintained after standard vertical ramus osteotomy as long as it was pedicled to the lateral pterygoid muscle and the articular capsule.

Biologic Basis for the Sagittal Split Osteotomy of the Mandible

Bell WH, Schendel SA: Biologic basis for modification of the sagittal ramus split operation.* J Oral Surg *35: 362–369, 1977

In 1977, Bell and Schendel published an experimental animal study to analyze the biologic basis for vascularization, revascularization, and bone healing in conjunction with sagittal ramus split procedures (Fig. 2-43). Ten adult rhesus monkeys were used. In each animal, on one side, the procedure was completed with complete subperiosteal stripping on the medial and lateral sides of the ramus osteotomy segment. On the contralateral side, the maximizing of the soft-tissue attachments on the medial and lateral side of the osteotomies was carried out. The animals were sacrificed at specific postoperative intervals (immediately or at 1, 2, 3, 6, 12, or 24 weeks). Microangiograms and histologic slides were reviewed at each time interval. The results of the experimental study confirmed that the Obwegeser technique of sagittal ramus osteotomy was biologically sound. Intraosseous ischemia and osteonecrosis were dramatically reduced when the mucoperiosteum and the pterygomasseteric sling were maintained to the repositioned proximal segment.

Biologic Basis for a "One Tooth" Dento-Osseous Segmental Osteotomy

Bell WH, Schendel SA, Finn RA: Revascularization after surgical repositioning of one-tooth dento-osseous segments.* J Oral Surg *36:757–765, 1978

In 1978, Bell, Schendel, and Finn published an experimental animal study to analyze the biologic basis for wound healing and revascularization after "one-tooth" dento-osseous segmental osteotomies in six adult mongrel dogs**.** Half of the experimental animals underwent a two-stage (single-tooth dento-osseous segment) approach, whereas the other group underwent a one-stage (single tooth dento-osseous segment) approach. The animals were sacrificed at specific postoperative intervals (3 days or 1, 3, 4, or 8 weeks). Microangiograms and histologic slides were reviewed. The data showed early transient vascular ischemia, minimal osteonecrosis, and osseous union between most of the osteotomized segments. The study parameters showed that necrosis occurred at a few of the interdental osteotomy sites. The authors stated that the "excessive removal of interseptal and interradicular bone may cause protracted bone healing and have a destructive effect on the periodontium."[33] The authors cautioned that the single-tooth dento-osseous segments were critically dependent on the preservation of viable circulation through the soft-tissue attachments to the underlying bone. This was by way of a freely anastomosing vascular plexus of the gingiva, the palate, the periodontium, and the dental pulp.

Biologic Basis for the Oblique Osteotomy of the Chin

Storum KA, Bell WH, Nagura H: Microangiographic and histologic evaluation of revascularization and healing after genioplasty by osteotomy of the inferior border of the mandible.* J Oral Maxillofac Surg *48:210–216, 1988

monkeys. These studies indicated that an intra-oral pedicled genioplasty involving an osteotomy of the inferior mandibular border maintained circulation and osseous viability after the manipulation and repositioning of the chin segment (Fig. 2-44). Circulation to the dental pulp was not discernibly affected.[182]

Biologic Basis for the Le Fort I (Down-Fracture) Osteotomy with Segmentation

Bell WH, You ZH, Finn RA, Fields RT: Wound healing after multisegmental Le Fort I osteotomy and transection of the descending palatine vessels. **J Oral Maxillofac Surg *53:1425–1433, 1995***

In 1995, Bell and colleagues completed a clinically analogous four-segment LeFort I (down-fracture) osteotomy through a circumvestibular incision via the Obwegeser technique in nine adult rhesus monkeys. The animals were sacrificed after surgery on day 0, 3, 7, 14, or 28. Revascularization and bone healing were studied by microangiographic and histologic techniques. The findings indicated that the palatal mucosa, the labial–buccal gingiva and mucosa provide adequate nutrient pedicles for Le Fort I down-fractured segmental osteotomies accomplished through a circumvestibular incision. It was documented that segmentalization, the stretching of the vascular pedicles (within physiologic limits), and the transection of the descending palatine vessels have only transitory discernable effects on revascularization and bone healing.

Hans G. Luhr: Development of Plate and Screw Fixation for Craniomaxillofacial Surgery*

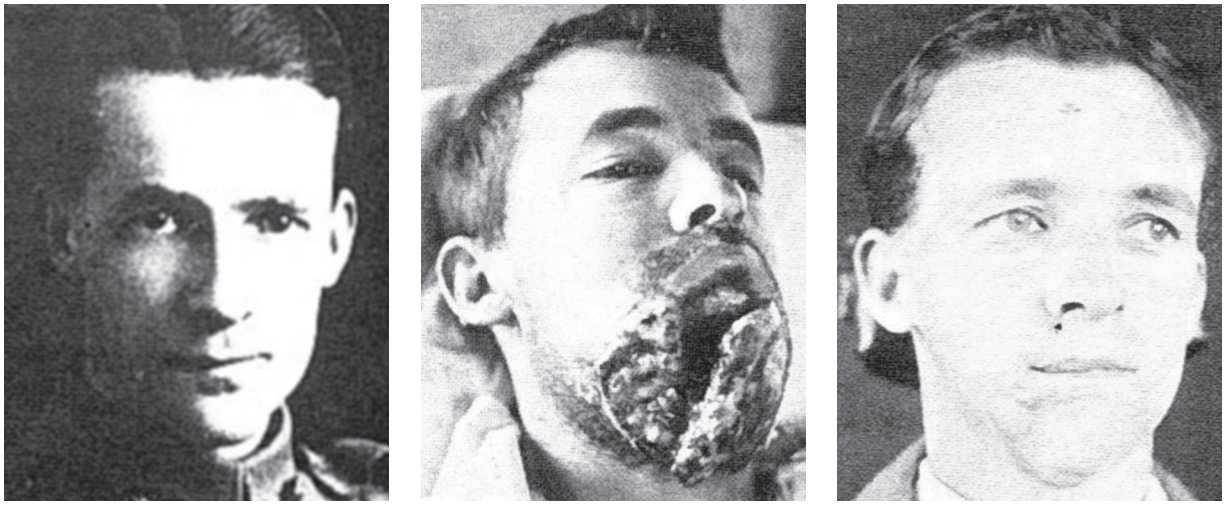
Hans Luhr was born in Germany in 1932. Like so many others during this time, his childhood years were disrupted by World War II. He graduated from the University of Bonn with a degree in medicine in 1958 at the age of 26, and he went on to complete a degree in dentistry in 1960. He worked as a ship's physician, and he then completed his postgraduate training and research in general pathology at the University of Bonn. In 1961, after receiving a public health scholarship award from the German Developing Aid Program, he served as a dentist in charge of a mobile unit that provided aid in the hinterland of Liberia in Western Africa.

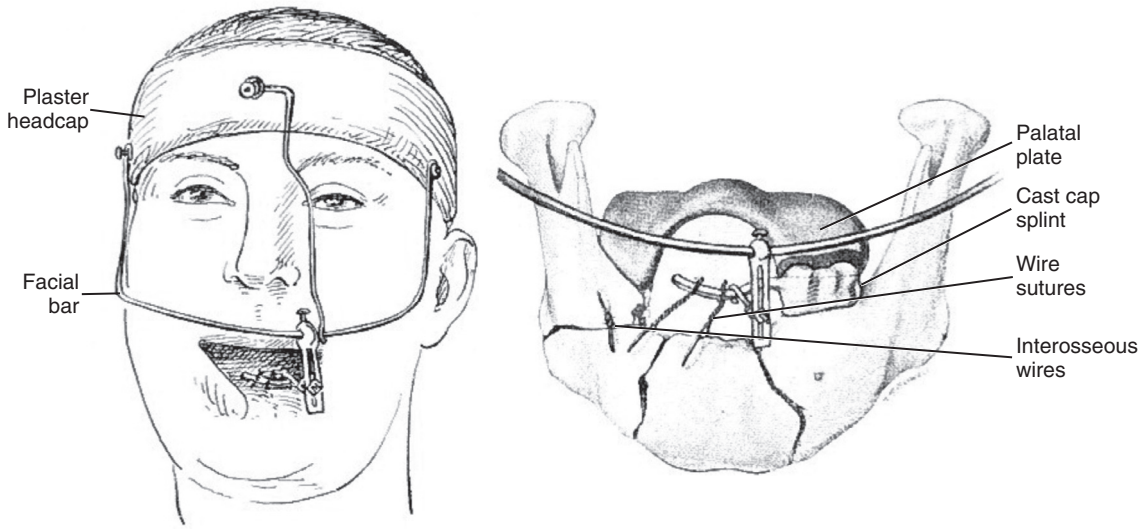
In 1963, Luhr began his training in maxillofacial surgery under the direction of Professor Karl Schuchardt. At that time, the Hamburg unit was considered the most prestigious in Germany. It was a regional maxillofacial trauma center, and, because Schuchardt had pioneered segmental osteotomies of the maxilla, there was much activity concerning jaw deformities with malocclusion. Schuchardt had also developed the acrylated arch bar, which was considered the treatment of choice for most mandibular fractures as well as for stabilization after elective mandibular osteotomies. Until Obwegeser described the Le Fort I down-fracture procedure with full mobilization, the Schuchardt method of horizontal Le Fort I osteotomy without pterygoid–maxillary disjunction was the procedure of choice. The incompletely mobilized maxilla was then managed by a "roll extension" and the application of 1.5 kg of weight via a sack of sand that was attached over the end of the hospital bed (Fig. 2-45). Disimpaction was gradual and

*Please note that this section was reviewed for accuracy by Dr. Luhr.

occurred over a 2-week period. When the preferred occlusion was finally realized, the jaws were secured with IMF.

Although it was clear that interosseous wire fixation was not rigid enough to counteract the masticatory muscle forces, it and other methods of fixation (e.g., plaster head cap with reinforced bar, palatal plate, cast cap splint, wire suture) were all that was known for the treatment of mandibular fractures and elective osteotomy stabilization (Fig. 2-46). Extended periods of IMF were also applied in an attempt to achieve healing. With these limited fixation and immobilization methods, complications such as osteomyelitis and nonunion frequently occurred, especially in the mandible. Skeletal wire suspension via the "belt-and-suspenders approach" had been introduced by Milton Adams in 1942 for the added stabilization of midface fractures, and this approach was later applied to elective jaw (orthognathic) osteotomies (Fig. 2-47).[1] These suspension wires were occasionally supplemented by threaded Steinmann pins as clinicians searched for improved ways of establishing stable fixation. Long periods of IMF continued to be the workhorse of immobilization in an attempt to achieve bony union of the jaws. Prolonged periods of limited mouth opening had negative effects on speech, breathing, chewing, swallowing, hygiene, and temporomandibular joint mobility. As a resident in training, Dr. Luhr viewed these maxillofacial challenges with fresh eyes. Appreciating the limitations and hazards of these methods of immobilization and with background knowledge of what was known at the time about long bone fractures, he hypothesized that the addition of compression across a mandibular fracture would

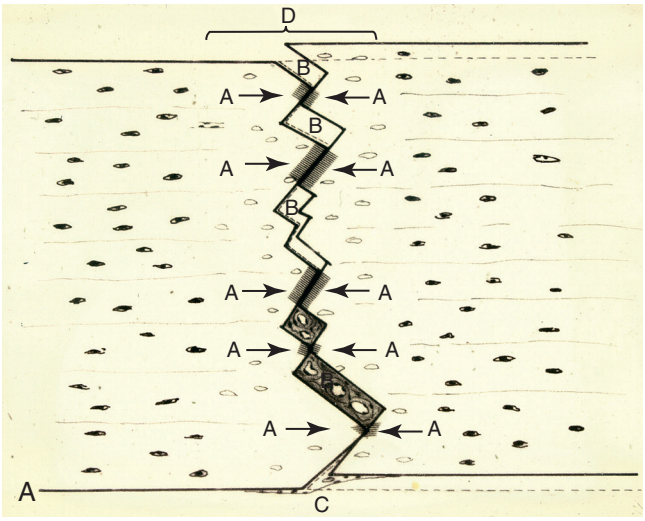




• **Figure 2-46** Kazanjian published an example of his management of a complex facial injury that was sustained by a soldier during World War I. The wound involved the soft tissues and skeletal structures of the face. Kazanjian used a combination of a plaster head cap, a facial bar, a palatal plate, cast cap splints, wire sutures, and interosseous wires to establish bony healing and soft-tissue maintenance. *From Kazanjian VH, Converse EJ:* The surgical treatment of facial injuries, *Baltimore, 1949, The Williams and Wilkins Company.*

provide the necessary interfragmentary stability and eliminate the need for intermaxillary fixation. With research interests in the biomechanics of bone healing and jaw fracture management in particular, Luhr established an animal laboratory to study these issues. His experimental dog model involved a traumatically induced mandibular fracture. The fracture model confirmed that interfragmentary pressure created by a compression bone plate was at least partially maintained during the healing period (i.e., approximately 50% at 4 weeks). Further experiments by Luhr determined that the use of compression increased the rate of strength during fracture union as compared with fixation techniques without the use of compression. Interestingly, Luhr found that, with an actual fracture model, the histologic pattern of primary bone healing differed significantly from the descriptions by Schenk and Willenegger (i.e., Association for Osteosynthesis/Association for the Study of Internal Fixation investigators), who used a "saw-cut" tibia osteotomy dog model.[129] During healing, these researchers observed the primary penetration of the osteotomy line via an ossification process that originated predominantly or exclusively in the cells and vessels within the Haversian canals. They termed this process *intracanalicular osteogenesis,* and they also called it *contact primary bone healing.* In their "saw-cut" tibia osteotomy dog model, the bone surfaces were in direct apposition to one another as fusion occurred. This was in contrast with "microgap healing," which was described by Luhr in the mandible fracture model (Fig. 2-48, *A*). Luhr's experimental model more closely simulated a real-life mandibular fracture. He found that the microscopic reduction of the fracture did not occur, despite the fact that the fracture appeared to the clinician to be grossly reduced. Small gaps still existed between the opposing bone spicular surfaces. Blood vessels and cells that originated in the endosteal cavity and in the periosteal side first invaded the microgaps between the opposing spicular surfaces. Lamellar bone was then deposited on the partially

• **Figure 2-47** An illustration of Adams suspension wires used to stabilize a midface fracture. In the past, this was a common method that was used in an attempt to immobilize a midface fracture.



• **Figure 2-48 A,** A schematic diagram of microgap healing at the microscopic level after the compression osteosynthesis of an experimental mandibular fracture in a dog. Although the fracture looks reduced at the time of surgery, microscopically, there were discrete areas of contact and separation between the fracture ends. The regeneration of bone took place in the non-contacting areas. Blood vessels had grown in both from the endosteal cavity and the periosteal side. Lamellar bone is deposited at the partially devitalized marginal fracture ends *(C)* with empty lacunae. **B,** Primary lamellar bone is deposited on the partially devitalized fracture ends around the blood vessels (cross-sectioned), which had grown in from the endosteal cavity and the periosteal side. This is a microscopic slide from 4 weeks after the compression osteosynthesis of an experimental mandible fracture in a dog. *From Luhr HG: Callus symposion.* Nova Acta Leopold *44:85–93, 1976.*

devitalized bone within the small interfragmentary gaps, and it soon filled up the microgaps and united the fracture segments (Fig. 2-48, *B*). As soon as 4 weeks later, the fracture was already clinically solid. The Haversian system contributed only to the late remodeling of the whole fracture zone, which could take several months. However, "gap healing" was seen with regularity, and it is viewed as a form of primary bone healing.

After confirming its success in experimental animals, Luhr was the first to apply maxillofacial compression osteosynthesis in a human. He did this on an edentulous woman who had sustained bilateral body fractures in an atrophic mandible (Fig. 2-49).[127] Within 6 months of this initial success, Luhr used similar compression osteosynthesis techniques on mandibular fractures in 16 additional patients, all with good results. He immediately saw the value of "self-tapping screws" in maxillofacial surgery. However, this went against the grain of general orthopedic surgeons, who at the time were beginning to use compression osteosynthesis for long bone injuries. They preferred to "pretap" the bone before the placement of fixation screws. Dr. Luhr chose Vitallium as a material, because it was a corrosive-resistant cobalt/chromium/molybdenum alloy with good strength. The small plates that he designed for use in the mandible were first modeled in wax, and they were then cast at a private dental lab. He would grind eccentric holes into each Vitallium fixation plate with the use of a diamond bur to complete the required design (Fig. 2-50). When drilling holes in the bone for the placement of self-tapping screws, Dr. Luhr initially used a hand-drill technique, because low-speed drills were not available in the operating room at that time. In 1968, Luhr reported on his initial consecutive series of mandibular fractures that involved the use of compression plating.[127] The Luhr Maxillofacial Fixation System was then manufactured by Howmedica in 1969.[133] Remarkably, all of the commercially available plate configurations in this system were designed by Luhr himself. He first completed pencil drawings to scale, and these served as design patterns for the manufacturer. This was true for all of the plating systems that Luhr introduced over the following two decades.

In January 1970, Dr. Luhr was presented with a patient who had been operated on elsewhere to correct a developmental jaw deformity that was characterized by mandibular prognathism. A Dingman osteotomy technique with interosseous wire fixation had been used, and this was followed by 12 weeks of IMF. The result was osteomyelitis with extraoral fistulas and nonunion on both sides (Fig. 2-51). Dr. Luhr initially removed the involved tooth at each osteotomy site and achieved drainage to manage the infection. He was able to stabilize each osteotomy site with the use of a compression plate with screws. A lower jaw arch bar was also left in place for 8 weeks to provide additional stability. With the stable direct fixation described, the intermaxillary fixation was immediately released, and healing was uneventful. This was likely the first case of plate and screw fixation used in orthognathic surgery. Although this case was not officially published by Dr. Luhr at the time, word quickly spread regarding this new technique of bone fixation for elective maxillofacial osteotomies.

The advantages of plate and screw fixation for orthognathic surgery soon caught on. Francois Michelet and colleagues from Bordeaux, France, published their results involving mini-plate fixation of the Obwegeser sagittal split osteotomy in 1971.[139] Two years later, mini-plate stabilization of elective maxillary osteotomies was also reported, with clear illustrations demonstrating how it should be done. Maxime Champy also described the use of mini-plates and monocortical screws for the treatment of mandibular fractures as well as the use of mini-plates and screws for elective Le Fort I osteotomies.[52,53] Bernd Spiessl preferred the use of lag screw techniques to stabilize sagittal split osteotomies.[176-178] He and others soon realized that, unless this technique was meticulously executed, the use of lag screws at the sagittal split osteotomy site could easily result in condyle dislocation with malocclusion as a result of the torquing effects. For the majority of surgeons, the philosophy of osteotomy fixation for sagittal splits soon shifted to the concept of "bicortical" (non–lag screw) technique in an attempt to avoid these complications. The so-called "positional screw" technique described by Lindorf[124,125] and Niederdellmann[146-148] gradually took hold. The potential risk of condyle dislocation with the application of mandibular osteotomy fixation during orthognathic surgery was recognized by Luhr.[132] To help prevent this occurrence, he designed a temporomandibular joint positioning device, which remains a viable alternative to the freehand positioning approach that is most frequently used today (see Chapter 15).

Publications describing the value of mini-plate and screw fixation after Le Fort I osteotomy were initially described by Michelet[139] and then by Champy,[52,53] Hörster,[97] Steinhäuser,[179] and Drommer and Luhr (1981).[73,74] Dr. Luhr reported on 17 cases of Le Fort I osteotomies using mini-plate and screw fixation specifically to correct the maxillary deformity in patients with cleft palates. During the late 1970s, the advantage of Dr. Luhr's L-shaped mini-plates (specifically designed for the fixation of Le Fort I osteotomy sites) became known. The L-shaped plates overcame the difficulties of establishing fixation along the dense bicortical vertical pillars (i.e., the piriform rim region and the maxillary buttress) of the maxilla while also gaining maximum horizontal fixation directly above the roots of the teeth on the dentoalveolar side.

Dr. Luhr reported one of the first bimaxillary orthognathic cases in which plate and screw fixation was used at all locations without the need for intermaxillary fixation after surgery. This was for a dental student who presented with a dentofacial deformity during the early 1980s. The operation included a maxillary Le Fort I osteotomy with advancement and bilateral sagittal split osteotomies of the mandible with setback. It is believed that the first bimaxillary orthognathic procedures that involved the use of rigid fixation in the United States were completed in 1983 by Dr. Harvey

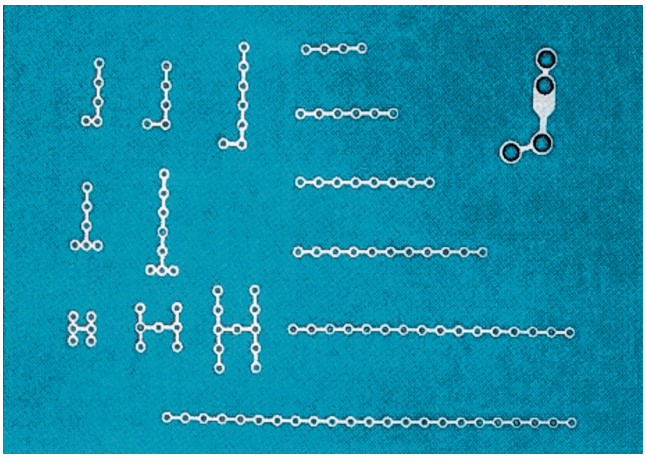
Rosen and Dr. Luhr (personal communication between Dr. Rosen and Dr. Luhr). In July 1983, after observing Dr. Luhr operating in Göttingen, Germany, Dr. Rosen was given a fixation set and encouraged to make use of it back home. In Philadelphia, Dr. Rosen completed bimaxillary surgery in a teenage girl with a cleft jaw deformity. He used Luhr plates and screws for the fixation of the Le Fort I and bilateral ramus osteotomies in November 1983. I served as Dr. Rosen's first assistant, and I was impressed by the new technology. The following month (December 1983), while serving as a visiting professor with Dr. Linton Whitaker at the University of Pennsylvania, Dr. Luhr demonstrated his techniques on a teenage girl with a long face mandibular deficiency anterior open bite who required a Le Fort I osteotomy with vertical intrusion and horizontal advancement as well as bilateral sagittal split osteotomies of the mandible with advancement. Under Dr. Whitaker, as a craniofacial surgery fellow, I was fortunate to have the opportunity to assist Dr. Luhr during this surgery. To rapidly disseminate the knowledge of Dr. Luhr's innovations, Dr. Whitaker organized a 1-day symposium at the University of Pennsylvania entitled "Fixation Options in Cranio-Maxillofacial Surgery." This event was attended by the leading craniofacial surgeons from throughout Canada, the United States, and Mexico. Recognizing the value of Luhr's application of plate and screw fixation to patient care, within months, this procedure became routine at their centers. Luhr's techniques were enthusiastically embraced by their residents in training and by the surgeons within their respective communities.

By the mid to late 1980s, the advantages of plate and screw fixation for use in a spectrum of elective craniofacial osteotomies, for fractures, and for tumor management was becoming known throughout the world. It was clear to Dr. Luhr that plates and screws of smaller dimension were required to accomplish clinical objectives, especially in the upper face. He designed the Luhr Micro-Fixation System, which is the smallest bone fixation system in the world; it includes screw diameters of as small as 0.8 mm and microplates of various design to match (Fig. 2-52).[133] The system's applicability to upper face clinical problems (e.g., cranial vault, orbit, zygomas, nose) was immediately clear and quickly adapted by craniofacial surgeons and neurosurgeons throughout the world.

Until the 1980s, chin osteotomy via Obwegeser technique fixation was accomplished with interosseous wires or circumsymphyseal wires. Some clinicians also used threaded Steinmann pins. During the late 1980s, Dr. Luhr published articles about a series of genioplasties in which he used plate and screw fixation on a routine basis.[134] There were few complications, and the clinical success was remarkable (Fig. 2-53). Dr. Luhr found the plate and screw fixation techniques for chin osteotomy stabilization to be especially useful when vertical lengthening and interpositional grafting were required. In 1988, Dr. Rosen also published a successful series of osseous genioplasties involving vertical lengthening with the use of Luhr (rigid) fixation.[168]



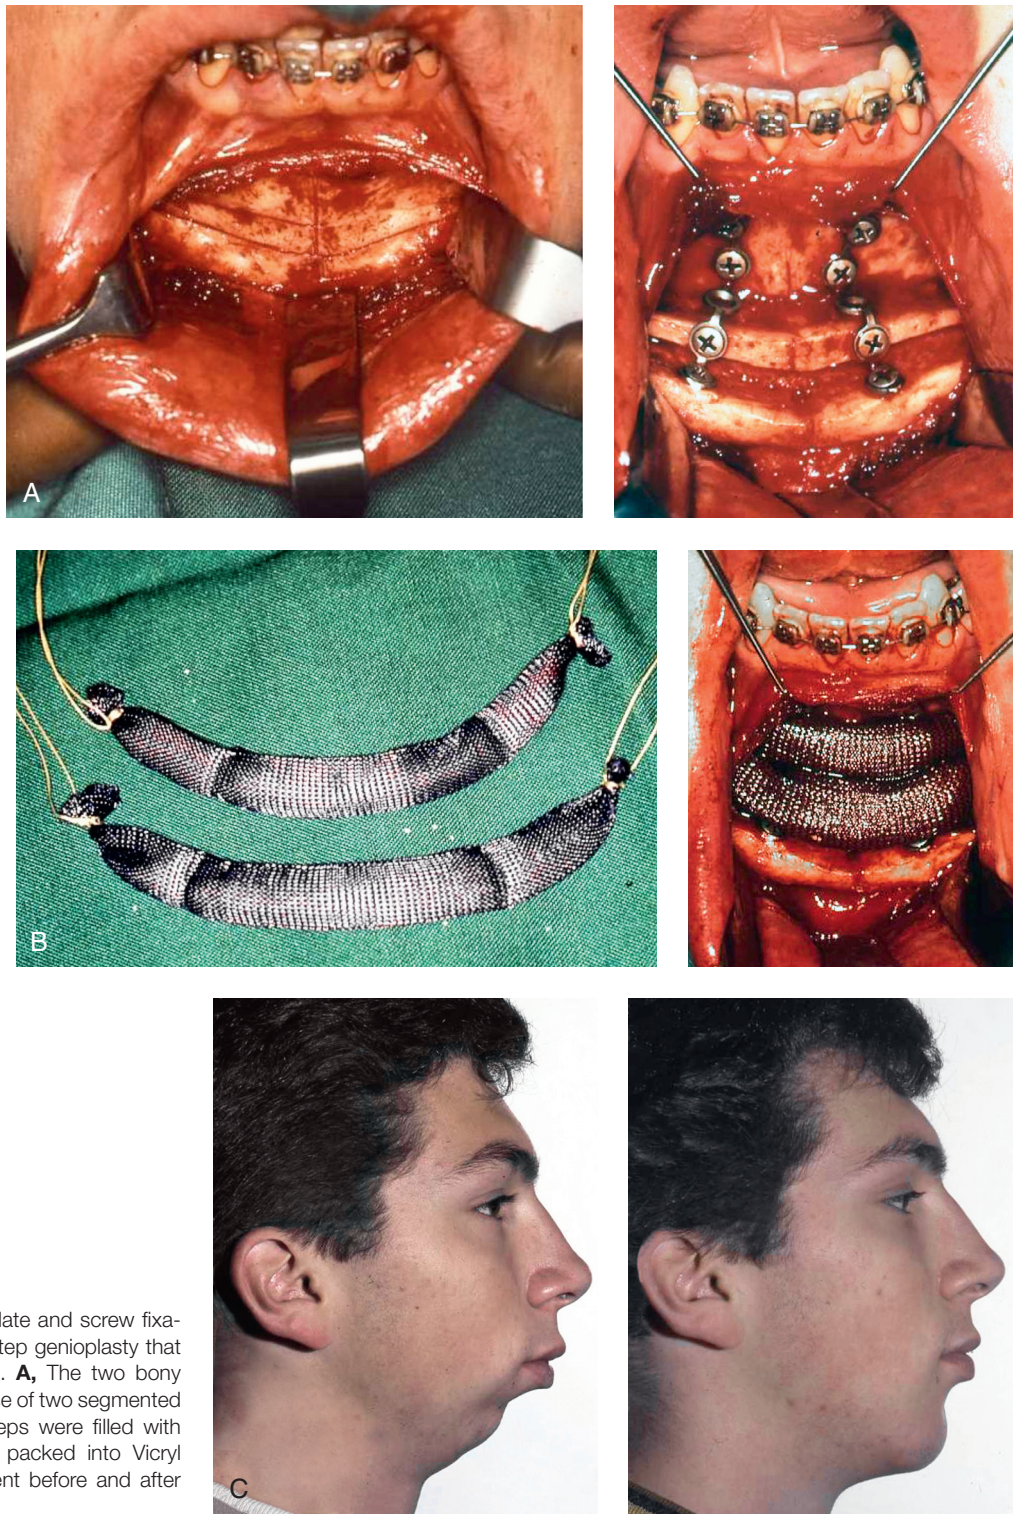
• **Figure 2-52** The first microplates designed by Dr. Luhr. A typical mini-plate from the time is shown in the upper right corner to demonstrate the difference in size. *From Luhr HG: Indication for use of a microsystem for internal fixation in craniofacial surgery.* J Craniofac Surg *1:36, 1990, Figure 2.*

As professor and head of the Department of Maxillofacial Surgery at the University of Göttingen, Dr. Luhr continued primate laboratory research and provided care to patients who had sustained facial trauma, who presented with dentofacial deformities, and who arrived with a spectrum of head and neck tumors until he retired from clinical practice in 2000. During this time, he published more than 200 scientific articles and book chapters. He continues to serve as Professor Emeritus in Maxillofacial Surgery at the University of Göttingen.

Throughout the 1960s and into the 1990s, Dr. Luhr stimulated a generation of craniomaxillofacial surgeons to embrace plate and screw fixation for trauma, elective osteotomies, and tumor management.[127-134] Luhr's initial ideas and commercially available fixation system served as a springboard for many of today's craniomaxillofacial innovations. Stable plate and screw fixation is one of the most significant advances in craniomaxillofacial surgery to have occurred during the 20th century. On the basis of his laboratory research, technical innovations, and clinical contributions, it is right to consider Dr. Luhr "the father of rigid fixation."

Paul Louis Tessier: Development of Craniofacial Surgery[101,215,216]

Paul Tessier (1917-2008) was born into a family of wine merchants in Héric on France's Atlantic Coast (see Fig. 2-30). He was an only child, and he had no family background in medicine. It has been stated that his initial ambition was to join the Navy, but he was excluded from this by early ill health. Because of his love for the outdoors, he also considered a career in forestry. In 1936, at age 19, he entered medical school. However, just halfway through his



• **Figure 2-53** The advantage of plate and screw fixation is demonstrated via a double-step genioplasty that resulted in a 20-mm advancement. **A,** The two bony segments were stabilized with the use of two segmented mini-plates and screws. **B,** The steps were filled with hydroxyapatite granules that were packed into Vicryl sacks. **C,** Profile views of the patient before and after surgery. *Courtesy Hans Luhr.*

studies, he became a prisoner of war in 1940. While he was interred, he became critically ill with a typhoid infection, but he eventually recovered. When he was released, he finally receiving his Doctor of Medicine degree from the Faculté de Médecine de Paris in 1943. When he came to Paris in 1944 (because the U.S. 8th Air Force had destroyed the hospital that he worked at in Nantes), Tessier worked with Maurice Virenque, a maxillofacial surgeon, at Hôpital Puteauz. After the war, the service moved to Foch, where there were, in essence, two maxillofacial services: one with Virenque and Tessier and one with Gustave Ginestet, an officious martinet who held the rank of General in the French Army. After Virenque died, Ginestet wrote Tessier several letters forbidding him to perform any maxillofacial

surgery; his only function was to be running the burn service. Tessier ignored Ginestet, but many of his methods of interlocking bone fixation were the result of the fact that Ginestet controlled the dental lab and forbade the technicians to provide any help to Tessier. Jacques Dautrey, who was Tessier's friend but who was also on Ginestet's service, used to sneak in to help Tessier.

Between 1946 and 1950, Dr. Tessier made yearly visits to England to observe Harold Gillies, Archibald McIndoe, and others whose advances in plastic surgery in response to severe military injuries were ongoing. Through his observations and his passion to find solutions to complex reconstructive problems, Dr. Tessier began to find innovative ways to perform osteotomies for the correction of congenital midface retrusion but without the problems that had plagued the performance by his mentor Harold Gillies. By the mid 1950s, Tessier had become the head of his department in Paris. He was consulted in 1957 by a young man with a facial deformity of "monstrous aspect" who was found to have Crouzon syndrome.[186] The patient's facial deformities included severe orbital dystopia/eye proptosis, midface deficiency/malocclusion, and obstructed breathing. Dr. Tessier was aware that Gillies had completed an elective Le Fort III osteotomy on a young adult with Crouzon syndrome who had a moderate degree of proptosis and midface deficiency (Fig. 2-54). Dr. Gillies was reported to be discouraged with the eventual outcome and had recommended to others "never to do it."[82]

Tessier was undeterred, and he set out to solve the problem initially by performing an anatomic study of dry skulls. For access to the anatomy laboratory, he traveled by train in the evenings to his medical school in Nantes. After his late-night cadaver dissections, he returned during the early hours for the next Parisian working day. His painstaking preparatory work paid off when he successfully advanced his patient's face by 25 mm and achieved stability with the novel use of bone grafts (which Gillies had not used), improved osteotomy design, incision placement, and immobilization techniques, including use of an external fixation apparatus (Fig. 2-55).

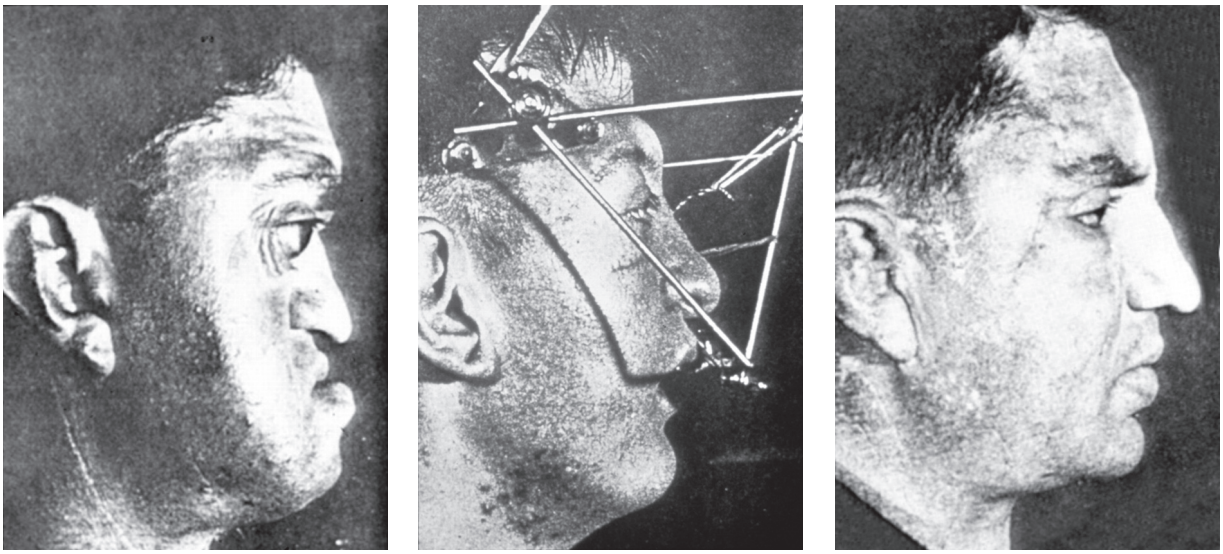
Dr. Tessier's next advance was to devise a technique for separating the orbits from the skull, thereby allowing for the relocation of the orbits and eyeballs for the protection of vision and improved aesthetics without damaging the brain or the eyes in the process. Working with Gerard Guiot, a neurosurgeon, Tessier took 3 more years to perfect his technique, which included the making of the bony cuts through the skull base by what soon became known as the "Tessier intracranial approach" to the orbits and the midface.

The surgical procedures developed by Tessier were shown to the world at a presentation that he made in Rome at the International Plastic Surgery Meeting in 1967.[187] The techniques were so revolutionary that Tessier sought to establish their validity before continuing further. In the most humble and unique way, Tessier invited prominent surgeons from around the world to observe him operating live so that he could demonstrate these techniques before a distinguished

• **Figure 2-54** Gillies published the results of a Le Fort III osteotomy that was completed in 1942 for an adult with Crouzon syndrome. *From Gillies H, Harrison SH: Operative correction by osteotomy of recessed malar maxillary compound in case of oxycephaly.* Br J Plast Surg *3:102, 1950.*

international group of his peers. He asked for their vote on whether his demonstrated surgical techniques had a place in the practice of surgery. The resounding positive responses of his peers were clear evidence of their support and approval. During the late 1960s and throughout the 1970s, Dr. Tessier developed all of the basic procedures and essential techniques that are currently used to perform what has come to be known as *craniofacial surgery,* including the transcranial and subcranial correction of orbital dystopia such as orbital hypertelorism; the correction of midface deficiency or deformity among patients with conditions such as Crouzon syndrome and Apert syndrome; the correction of facial deformities associated with such conditions as Treacher Collins–Franceschetti syndrome; and the description and correction of the spectrum of oro-ocular clefts. The impact of Dr. Tessier's work has affected every surgical specialty that seeks solutions to head and neck problems, including plastic surgery, otolaryngology/head and neck surgery, ophthalmology, neurosurgery, trauma surgery, and oral and maxillofacial surgery.

By the late 1960s, Paris become the birthplace of the new specialty of craniofacial surgery, where visitors would flock to observe Tessier's techniques and approach to problem



• **Figure 2-55** Tessier reported early results with an intracranial Le Fort III osteotomy.

solving. Dr. Tessier began traveling to the United States and England to demonstrate his procedures in cities such as Philadelphia, Chicago, Kansas City, Houston, Boston, Norfolk, and London.[185] Dr. Tessier's work became so far reaching that, by the 1990s, virtually everyone performing craniofacial procedures was either trained by Dr. Tessier himself or by surgeons whom he had trained.

Dr. Tessier's contributions cannot be overestimated.[184-196] His basic innovations to safely separate the orbits and the midface from the base of the skull with the use of an intracranial approach satisfy the needs for exposure during complex surgery and craniofacial reconstruction. His techniques have revolutionized the treatment of birth defects of the head and neck; tumors of the midface, orbit, and skull base; severe facial deformities and asymmetries; craniofacial trauma; and complex infections. In response to questions about what inspired his unique approach to problem solving, Tessier would quote Guiot's response: "Pourquoi pas?" This phrase—which is translated into English as "Why not?"—became the motto of the International Society of Craniofacial Surgery, founded in 1983, of which Tessier was invited to be Honorary President.

Dr. Tessier understood the importance of interspecialty collaboration, because "no one man could master all techniques and be an island onto himself" (personal communication). The recognition that individuals with complex surgical problems and deformities of the head and neck often require a team approach did not deter him. Tessier's painstaking preparatory work to achieve the best results for each and every patient and his insistence on the highest level of collaborative care was the mark of the man. He did not settle for mediocrity, and he expected the same commitment from others. This was true in all aspects of his professional and personal life. Hard work, determination, intelligence, focus, innovation, meticulous organization and planning, and—above all—imagination were the characteristics that Tessier demonstrated in his everyday life and that he appreciated in others.

Conclusions

Modern practicing orthodontists and maxillofacial surgeons have learned much from the pioneers in this field. We stand on the shoulders of the giants who came before us. Thanks to them, when evaluating an individual with a dentofacial deformity, we are now able to safely and reliably offer effective treatment to achieve long-term occlusal stability, periodontal health, an improved upper airway, and enhanced facial aesthetics in most cases. Even so, further innovations are expected from those who will come next.

Definition and Prevalence of Dentofacial Deformities

JEFFREY C. POSNICK, DMD, MD

- Prevalence of Jaw Deformities and Malocclusion
- Orthognathic Procedures Performed on Hospitalized Patients in the United States
- Conclusions

The term *dentofacial deformity* refers to significant deviations from normal proportions of the maxillomandibular complex that also negatively affect the relationship of the teeth within each arch and the relationship of the arches with one another (occlusion).[2,4,5,8,11,14,15,17,18,21,22,25,27,31,36,37,40,52,54] The affected individual will have varied degrees of compromise in head and neck functions related to breathing, swallowing, speech articulation, chewing, and lip closure/posture. Effects on the temporomandibular joints, the periodontium, and the teeth themselves may also occur.[24,25,28,33,34,38,55] The presenting facial disproportion will, in general, have at least some negative effects on psychosocial health.[16,39,56,57]

Racial variations with regard to the incidence of facial dysmorphology and the resulting malocclusion are also known to occur.[59,64] Definitions of acceptable levels of deviation from normal continue to be questioned by both clinicians and patients.[7,26,30,32,35,58,61,62] Over the years, the National Center for Health Statistics has collected data and the Research Council has held multidisciplinary conferences to focus attention on these issues.[6,12,19,20,29,41-51,53,63]

Surgery to reposition the jaws (i.e., an orthognathic procedure) as part of an interdisciplinary approach is often recommended to manage the related skeletal, dental, and soft-tissue dysfunctions and concerns.[3,13,23,60,66] Speech therapy, dental work, orthodontics, and surgical procedures alone are generally inadequate as isolated treatment modalities.

A dental clinician who is asked to evaluate the affected individual must ask himself or herself, "Are the problems too severe to be most effectively managed with orthodontics and dentistry alone?" A cosmetic surgeon who evaluates the same patient must ask himself or herself, "Will limited soft-tissue or augmentation procedures alone be sufficient to properly manage the presenting dysmorphology and to address functional aspects?"

If the discrepancy in the size or position of the jaws as they relate to each other and to the upper facial skeleton results in significant facial disproportion and also negatively affects certain head and neck functions (e.g., speech, swallowing, chewing, lip closure and posture, breathing), then it should not be ignored. It would be misguided to consider orthodontics alone to alter the occlusion without fully informing the patient and his or her family of the preferred biologic approach to management (i.e., orthodontics and jaw surgery). Likewise, it would be avoiding the obvious for the cosmetic surgeon to recommend either soft-tissue aesthetic or skeletal contour procedures without discussion of the presenting malocclusion, airway dysfunction, and overall facial disproportion. The treatment recommended to the patient and his or her family should not be limited by the skill set of the initial consulting clinician.

Facial disproportion observed in a child may at times be self-correcting. For example, apparent mandibular deficiency that is present before the pubertal growth spurt may normalize. In some cases, the maxilla or mandible may be induced to grow a few millimeters, more or less, through dentofacial orthopedics. However, major transformation of the jaws with the use of growth-modification techniques cannot be expected. Proffit has pointed out that, even with the well-intended aim of dentofacial orthopedics to alter jaw growth, as a result of anchorage requirements and biologic realities coupled with the practical desire of the orthodontist to "correct the occlusion," the treatment generally results in the displacement of the teeth in the direction of correcting the occlusion rather than the jaw relationships.[53] The term *dental compensation for the skeletal discrepancy* is universally understood to explain this treatment approach. Orthodontic-introduced dental compensation for the occlusion will hinder the eventual skeletal (orthognathic) correction if this is later required or requested.

Informed consent from the patient or his or her family is strongly recommended before embarking on a compromised treatment plan. For example, if a child is recognized to have an underdeveloped mandible with a Class II malocclusion and standard growth modification is attempted, it may be difficult for the orthodontist to prevent at least some retraction of the upper incisors and the forward displacement of the lower teeth. This may result in an "improved" occlusion, but it may also potentially involve long-term negative effects on periodontal health (e.g., labial cortical bone stripping), the airway (e.g., retroglossal obstruction), and facial aesthetics (e.g., a weak profile).[39,56,57] It also compromises the option of an orthognathic correction with the need to first "undo" the dental compensations through "redo" orthodontics (Fig. 3-1).

In the growing child who presents with a Class II malocclusion pattern, an active treatment approach is often offered by the orthodontist. This approach may attempt

• **Figure 3-1** A 21-year-old woman with a primary mandibular deficiency growth pattern requested a surgical consultation for a "weak chin." During her early teenage years, she underwent unsuccessful growth modification in an attempt to stimulate the forward projection of the mandible. This was followed by an orthodontic camouflage approach. The mandibular anterior dentition was flared forward. The history was significant for restless sleeping and a degree of daytime fatigue, which are suggestive of obstructive sleep apnea. Examination confirmed a retrognathic mandible with a Class II malocclusion. The mandibular incisors were crowded and procumbent. The family had hoped that a "chin implant" would be effective to manage the aesthetic effects. A sleep study confirmed obstructive sleep apnea (respiratory disturbance index = 18/hour). An orthognathic approach (Le Fort I, Sagittal splits, Osseous genioplasty) with redo orthodontic treatment including lower bicuspid extractions was recommended as the preferred method to improve the airway, to achieve long-term dental health, and to enhance facial aesthetics. **A,** Frontal facial and occlusal views. **B,** Profile facial view and lateral cephalometric radiograph.

to alter jaw growth and to correct the occlusion by means of the following: (1) functional appliance use (e.g., Frankel, Twinblocks) to stimulate sagittal growth of the mandible; (2) the possible extraction of maxillary premolars with orthodontic incisor retraction; (3) the use of headgear to restrain maxillary sagittal growth; and (4) the orthodontic forward displacement of the lower anterior teeth (Fig. 3-2). With the use of this approach, favorable facial results will be seen in only a very specific patient subgroup that includes those patients with true maxillary dental protrusion and a limited degree of mandibular retrusion. In these cases, the extraction of maxillary premolars with the retraction of the incisors to a corrected inclination in combination with the minimal forward displacement of the lower teeth may result in both favorable occlusion and acceptable facial aesthetics.

For the experienced surgeon and orthodontist, the accurate diagnosis of a dentofacial deformity will usually be clear after the initial examination and a review of standard records. A favorable correction through the effective

• **Figure 3-2** A 20-year-old man with a primary mandibular deficiency growth pattern requested a surgical consultation for a "weak chin." During his early teenage years, he underwent unsuccessful growth modification in an attempt to stimulate the forward projection of the mandible. This was followed by an orthodontic camouflage approach that included maxillary first bicuspid extractions to retract the anterior teeth. In addition, the mandibular anterior dentition was flared forward. His history was significant for heavy snoring, restless sleeping, and a degree of daytime fatigue, all of which are suggestive of obstructive sleep apnea. Examination confirmed a retrognathic mandible with a molar Class II deep bite malocclusion. The mandibular incisors were crowded and procumbent. The family had hoped that a "chin implant" would be effective to manage the aesthetic effects. A sleep study was recommended. An orthognathic approach (Le Fort I, Sagittal splits, osseous genioplasty) with redo orthodontic treatment was suggested as the preferred method to improve the airway, to achieve long-term dental health, and to enhance facial aesthetics. **A,** Frontal facial and occlusal views. **B,** Profile facial view and lateral cephalometric radiograph.

orthodontic alignment of the teeth in combination with the surgical repositioning of the jaw(s) will be the preferred approach.

Prevalence of Jaw Deformities and Malocclusion

U.S. Population Survey

As part of a large-scale evaluation of the health of the U.S. population, a National Health and Nutrition Examination Survey (NHANES III) was carried out between 1989 and 1994.[53] Starting with a sampling of 14,000 individuals, estimates of the incidence of malocclusion and its severity were made. The sample of individuals was carefully selected to provide weighted estimates for an approximate 150,000,000 people between the ages of 8 and 50 years who were members of black, white, and Latino American racial and ethnic groups. Those individuals outside of that age range (i.e., those younger than 8 years and older than 50 years), Native Americans, those living on military reservations, and some other specific population groups were excluded from this study. Data collected included the following:

- The alignment of the incisor teeth
- The horizontal position of the incisors (i.e., overjet or reverse overjet)
- The vertical overlap of the incisors (i.e., deep bite or open bite)
- The presence of posterior crossbite
- The presence of maxillary midline diastema

The Horizontal/Sagittal Dimension

This study provides useful information about preadolescent children (8 to 11 years old), adolescents (12 to 17 years old), and adults (18 to 50 years old) with reference to how the teeth fit together and, by inference, the prevalence of dentofacial deformities. When interpreting the data collected for the NHANES III study, it is important to consider that at least some degree of dental compensation for an existing jaw deformity normally occurs during growth and is expected to have been present at the time that the study measurements were taken. Therefore, it is unlikely that either the moderate or greater values of positive overjet or the mild to moderate values of negative overjet measured in the NHANES III study were found in individuals with "normal" jaw relationships. It would be safe to assume that any individual in the study with more than 7 mm of positive overjet has a jaw discrepancy that is characterized by mandibular deficiency (see Chapter 19). In addition, those with 2 mm or more of reverse overjet are assumed to have elements of maxillary deficiency in combination with relative mandibular excess (see Chapter 20).

The NHANES III study documents that extreme positive overjet is more frequent among children and that reverse overjet becomes more common among adults (i.e., after growth completion). This data confirms that, in some children, a late mandibular growth spurt not only corrects the excess positive overjet but actually causes it to become negative. Fortunately, in at least some of the children with an excess overjet, "catch-up" mandibular growth corrects the occlusion without overshooting the mark. The NHANES III study also documents that significant reverse overjet is more prevalent among blacks and Latino Americans as compared with whites. This confirms the more frequent dentofacial deformity growth pattern of maxillary deficiency in combination with relative mandibular excess that is seen among blacks and Latinos as compared with whites.

According to the NHANES III study, only a third of the members of the U.S. population have ideal (horizontal) anteroposterior incisor relationships, and another third of these individuals have a moderate overjet discrepancy (i.e., borderline jaw dysharmony). The remaining third have either a severe positive overjet or a reverse overjet malocclusion. It is reasonable to assume that a significant percentage of this subgroup (i.e., those with a severe positive overjet or a reverse overjet) have a jaw discrepancy that would benefit from orthognathic surgery. In reality, many individuals in this subgroup will be treated with compromised orthodontics (i.e., dental compensation) in an attempt to neutralize the occlusion without the benefit of an orthognathic correction. This will result in suboptimal facial aesthetics and the potential for occlusal instability, long-term periodontal sequela, and compromise of the upper airway.

The Vertical Dimension

According to the NHANES III study, only half of the U.S. population has an ideal vertical relationship of the incisors (i.e., 0- to 2-mm overbite). In the others, a deep bite in combination with mandibular deficiency or maxillomandibular deficiency is more prevalent among whites, and an open bite in combination with bimaxillary dental protrusion is more frequent among blacks. Interestingly, either a severe deep bite (≥5 mm) or a marked open bite (≥2 mm) was present in approximately 20% of children and 13% of adults. The extreme values of open bite that were measured in the study group likely represent either a long face growth pattern (i.e., vertical maxillary excess or mandibular deficiency; see Chapter 21) or bimaxillary dental protrusion (see Chapter 24). Interestingly, significant anterior open bite as part of a long face growth pattern is more prevalent among white Americans. The extreme values of deep bite in the studied individuals are likely to represent either a short face growth pattern (i.e., maxillomandibular deficiency; see Chapter 23) or a primary mandibular deficiency. Significant degrees of vertical discrepancy (deep bite or open bite) at the incisors ideally benefit from orthognathic surgery. When dental compensating orthodontic treatment is instituted rather than orthognathic correction, compromised facial aesthetics, occlusal instability, and periodontal sequela are more likely to occur.

U.K. Population Survey

An Index of Treatment Need was developed by the Swedish Dental Board to classify the severity of dental findings by the worst presenting characteristic.[33] This method tends to downplay the specific alignment of individual teeth. It is a classification system that looks more globally at facial proportions and head and neck function than at isolated dental details. For example, if you have a mild irregularity of the incisors and only a mildly excessive overjet, you are judged to have only a mild problem. In other words, the impact on the individual is not judged to be more severe, because there is a combination of two mild occlusal deviations from normal. Alternatively, if you have a 10-mm overjet, even if the teeth are aligned in each jaw, you are judged to have a severe problem.

Brook and Shaw made modifications to the Swedish classification and developed the Index of Treatment Need for malocclusion to be used as a grading system of dental health and functional indications for treatment.[9,10] The first part of their study was derived from the direct examination of occlusion and dental alignment. They defined five grades of treatment need, with Grade 1 representing little or no need for treatment and Grade 5 representing great need for treatment. The authors attempted to establish meaningful values for cutoff points between grades for each occlusal trait and to determine the quantifiable threat to the dentition if no treatment is provided. Grades 4 and 5 have characteristics that can result in a more severe impact on both facial aesthetic and dental aspects. These characteristics include the following:

Grade 5:
- Defects of cleft lip and palate*
- Overjet of more than 9 mm*
- Reverse overjet of more than 3.5 mm with reported masticatory and speech difficulties*
- Extensive hypodontia*
- Impeded eruption of the permanent teeth
- Submerged primary teeth

Grade 4:
- Extreme lateral or anterior open bites (>4 mm)*
- Increased overjet (>6 mm but ≤9 mm)*
- Reverse overjet (>3.5 mm with no masticatory or speech difficulties)*
- Reverse overjet of more than 1 mm with reported masticatory or speech difficulties
- Posterior crossbite with no functional occlusal contacts in one or both buccal segments
- Increased and complete overbite with gingival or palatal trauma
- Anterior or posterior crossbites with more than 2 mm of centric relation/centric occlusion discrepancy
- Severe contact point discrepancy (>4 mm)
- Less extensive hypodontia (e.g., one tooth per quadrant requiring preprosthetic orthodontics)
- Partially erupted teeth that are tipped and impacted against adjacent teeth
- The presence of supernumerary teeth

*Occlusal traits consistently found in association with a dentofacial deformity.

Individuals with extremes in positive overjet, reverse overjet, crossbite, and open bite as well as those with associated cleft lip and palate are considered to have Grade 4 and 5 conditions and judged to have problems that are severe enough that definitive treatment is needed. By inference, it is likely that a significant number of individuals with Grade 4 and 5 issues would ideally receive both orthodontics and jaw-straightening surgery.

The second part of the authors' overall assessment of treatment priority was to record the aesthetic impairment contributed by the malocclusion. The authors used the Standard Continuum of Aesthetic Need (SCAN) index as a rating scale.[16] The SCAN scale was constructed with the use of dental photographs from 1000 12-year-old children that were collected as part of a large multidisciplinary survey. Six non-dental judges rated these photographs on a 10-point visual analog scale. Both the aesthetic impairment component and the dental health component were part of the overall study.

The distribution of ratings for the Dental Health Indications Study conducted by Brook and Shaw were obtained from examination subjects (n = 222) who, at minimum, were felt to have a malocclusion to the extent that referral to a regional orthodontic center for advice or treatment was recommended.[10] Each study patient was then examined, and their available radiographs were reviewed by skilled clinicians. Both components of the index (i.e., aesthetic and dental) were applied, and the patients were also asked to give their own rating according to the SCAN scale. Interestingly, there was a high correlation (confirmed by intraexaminer and interexaminer error testing of the findings) between both components (i.e., aesthetic and dental) of the study.

The study results indicated that 19.2% of the subjects (44 of 222) were considered to have Grade 5 conditions. Interestingly, the distribution of ratings from Grades 1 through 5 that were obtained from the examination of a matched, random, unselected group of schoolchildren (n = 333) indicated that only 5.1% fell in the Grade 5 category. A Grade 5 score indicates severe malocclusion with a high need for treatment to establish dental health. Most of the traits listed as Grade 5 cannot be corrected with orthodontics alone, and orthognathic surgery would likely be recommended or at least considered. The Shaw study indicates that, in the United Kingdom, more than 5% and as high as 19% of children who have been referred to an orthodontist for evaluation are likely to have a malocclusion to the extent that orthodontics alone would not be the first choice for full correction (i.e., there is a need for orthognathic surgery).[10]

Orthognathic Procedures Performed on Hospitalized Patients in the United States

Venugoplan and colleagues completed a study with the aim of providing a nationally representative estimate of the number and type of orthognathic procedures performed on hospitalized patients in the United States.[65] Their data was obtained from the Nationwide Inpatient Sample (NIS) database from 2008 and included all hospitalizations for orthognathic procedures. The procedures were identified via the procedure code listed in the *International Classification of Diseases, 9th Revision, Clinical Modification.*[1] The NIS database is sponsored by the Agency for Healthcare Research and Quality, a division of the Department of Health and Human Services of the U.S. government. Ten thousand three hundred and forty-five (10,345) hospitalizations for orthognathic procedures were identified as occurring during the 2008 calendar year. The average age of these patients was 26.7 years, and female patients comprised 56.2% of all those who were hospitalized for these procedures. Whites, blacks, Hispanics, Asians, Pacific Islanders, and Native Americans and other races constituted 71.9%, 4.9%, 12.6%, 5.6%, 0.4%, and 4.6% of the hospitalizations, respectively. Private insurance plans were the primary payers (77.3%). Government insurance plans (i.e., Medicare and Medicaid) accounted for 13.4% of the patient mix, whereas 3.5% of patient paid privately (i.e., out of pocket), without the benefit of medical insurance.

Le Fort I osteotomy without segmentation accounted for 15.3% of the procedures; 45.8% of the procedures were Le Fort I with segmentation; and 31.7% of the procedures were ramus osteotomies of the mandible (e.g., sagittal split ramus osteotomies or vertical oblique osteotomies). It was found that 53.3% of the patients underwent one jaw surgery, whereas 36.8% likely underwent bimaxillary osteotomies. It would appear that only 9.2% of the patients underwent combined upper jaw, lower jaw and chin procedures. Only 0.7% underwent additional other simultaneous procedures, including such possibility as septoplasty, inferior turbinate reduction, neck liposuction, and the removal of wisdom teeth.

The pattern of jaw deformity for which the patient underwent orthognathic surgery could to a certain extent be delineated. It would appear that 33.1% of the skeletal patterns were Class III anomalies, whereas 23.8% involved skeletal Class II anomalies. The vast majority of orthognathic procedures were for the correction of routine dentofacial deformities. Approximately 10% of the orthognathic procedures were for the correction of a syndromal form of jaw deformity.

Ninety-six percent of patients were discharged routinely without the need for a "home health care facility" or transfer to either a long-term or acute-care facility. The mean length of hospital stay was 2.95 days, and the mean hospital bill generated costs of $47,348.00. This was assumed to include all costs related to the hospital, operating room, and anesthesia, but it did not include the surgeons' fees. The hospital bill generated did not necessarily correlate with the amount actually paid by either the third-party insurance company or the self-paying patient. Data regarding the actual payments is not available. From the available data, the total estimated hospitalization charges for orthognathic procedures carried out in the United States during 2008 were estimated to be $466.8 million (not including the surgeons' fees). Surgeons in "teaching hospitals" performed 67.1% of the procedures, and surgeons in "large-bed hospitals" performed 70% of the procedures. Hospitals in urban areas accounted for 97.4% of the hospital admissions.

It must be understood that the study by Venugoplan and colleagues did not capture those orthognathic procedures carried out either in an outpatient setting (i.e., not requiring admission to hospital) or procedures that were performed exclusively in a "surgicenter." These parameters were outside of the NIS database. It is estimated that as many as another 20% of orthognathic procedures were likely completed in these outpatient or surgicenter settings during this time period, which could result in 2000 additional patients.

Conclusions

The term *dentofacial deformity* refers to significant deviations from the normal proportions of the maxillomandibular complex that also negatively affect the relationship of the teeth within each arch as well as the relationships of the archs with one another (i.e., occlusion). The affected individuals will have varying degrees of compromise in their head and neck functions related to breathing, swallowing, speech, chewing, and lip closure and posture. A negative impact of the maxillofacial dysmorphology on psychosocial health is also to be expected. Studies confirm that, at a minimum, 5% of both the U.S. and U.K. general populations will have dentofacial deformities that are associated with severe malocclusion and that require orthognathic surgery. It is likely that as high as 19% of individuals who present for orthodontic assessment would ideally require not just orthodontics but jaw-straightening procedures as well.

Hereditary, Developmental, and Environmental Influences on the Formation of Dentofacial Deformities

JEFFREY C. POSNICK, DMD, MD

- Development of the Head and Neck
- Syndromes and Anomalies that Include Dentofacial Deformities
- Hereditary Tendencies in the Development of Dentofacial Deformities
- Environmental and Neuromotor Effects on Skeletal Growth
- Effects of Trauma on Skeletal Growth
- Effects of Tumors and Growths on Skeletal Growth
- Conclusions

The term *dentofacial deformity* is generally used to describe a significant disproportion of the jaws in association with malocclusion. It is estimated that, at a minimum, 5% of the population will have a discrepancy that falls into the developmental dentofacial deformity category. Another 45% of the population will fall into a much larger group of those with malocclusion but without what is considered a "notable" jaw discrepancy component.[2,3,5,56,65,72] After jaw growth is complete (i.e., 14 to 16 years of age in girls and 16 to 18 years of age in boys), the definitive reconstruction of a dentofacial deformity can go forward.

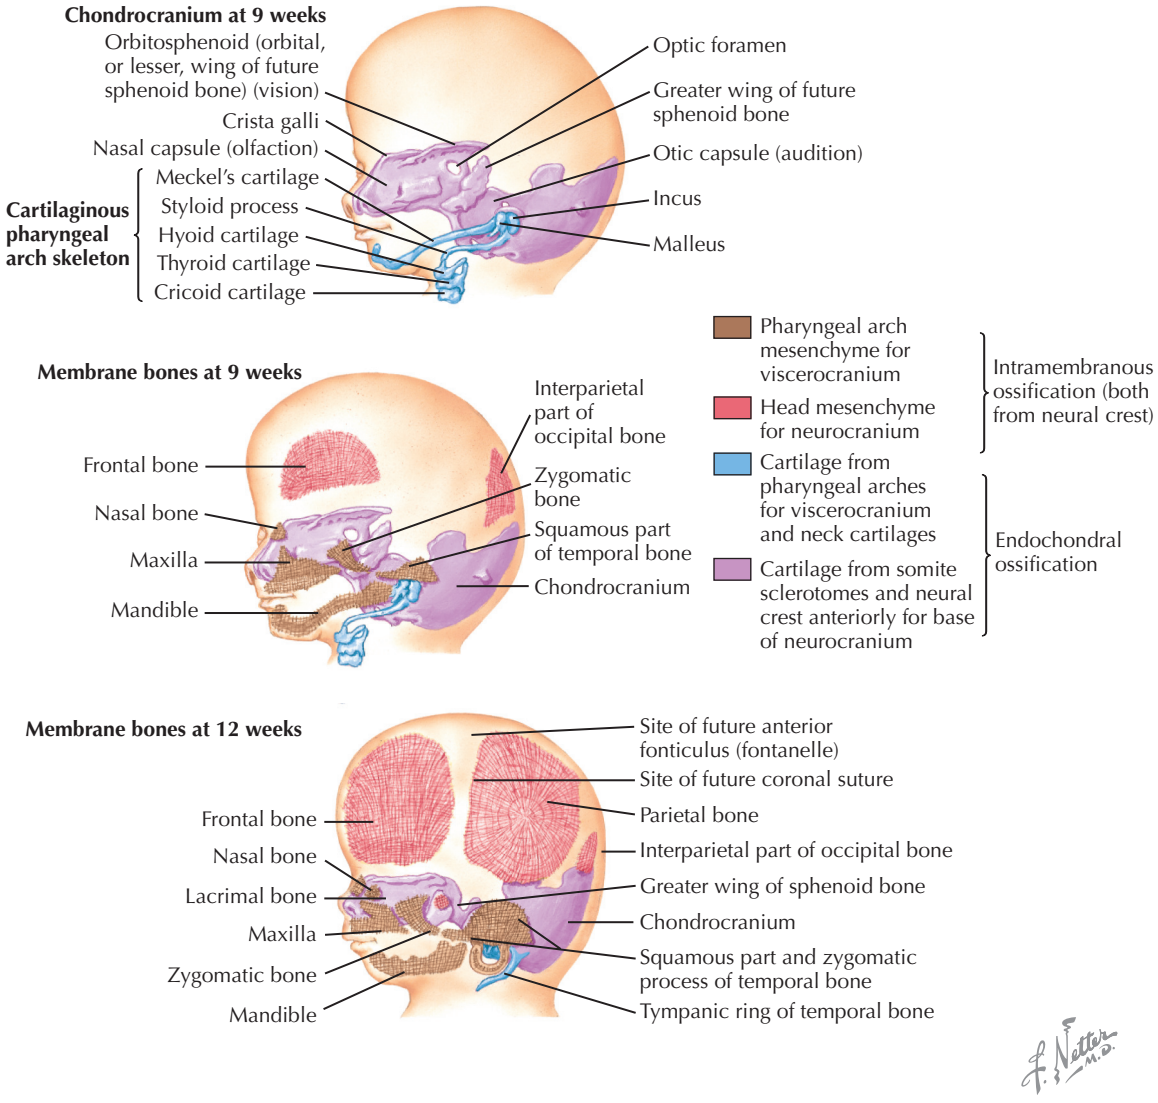
Knowing the etiology of a patient's jaw deformity can be important to the fundamental understanding of how and when to treat the problem. Knowledge of normal facial growth and development as well as the effect of any associated malformations (e.g., hemifacial microsomia with cervical spine anomalies) is useful both to limit complications during treatment and for family planning. Understanding the natural history of a condition that involves environmental influences may provide an opportunity to prevent or at least lessen the impact of the deformity. Knowledge of factors that influence facial skeletal growth and dental development (e.g., the muscles of the neck, tongue, and lips; breathing patterns) is important. Factors that are known to alter facial growth and cause jaw discrepancy can be subdivided to include the following: 1) known syndromes and anomalies; 2) hereditary tendencies; 3) environmental and neuromotor effects; 4) effects of trauma; and 5) effects of tumors or growths.

Development of the Head and Neck

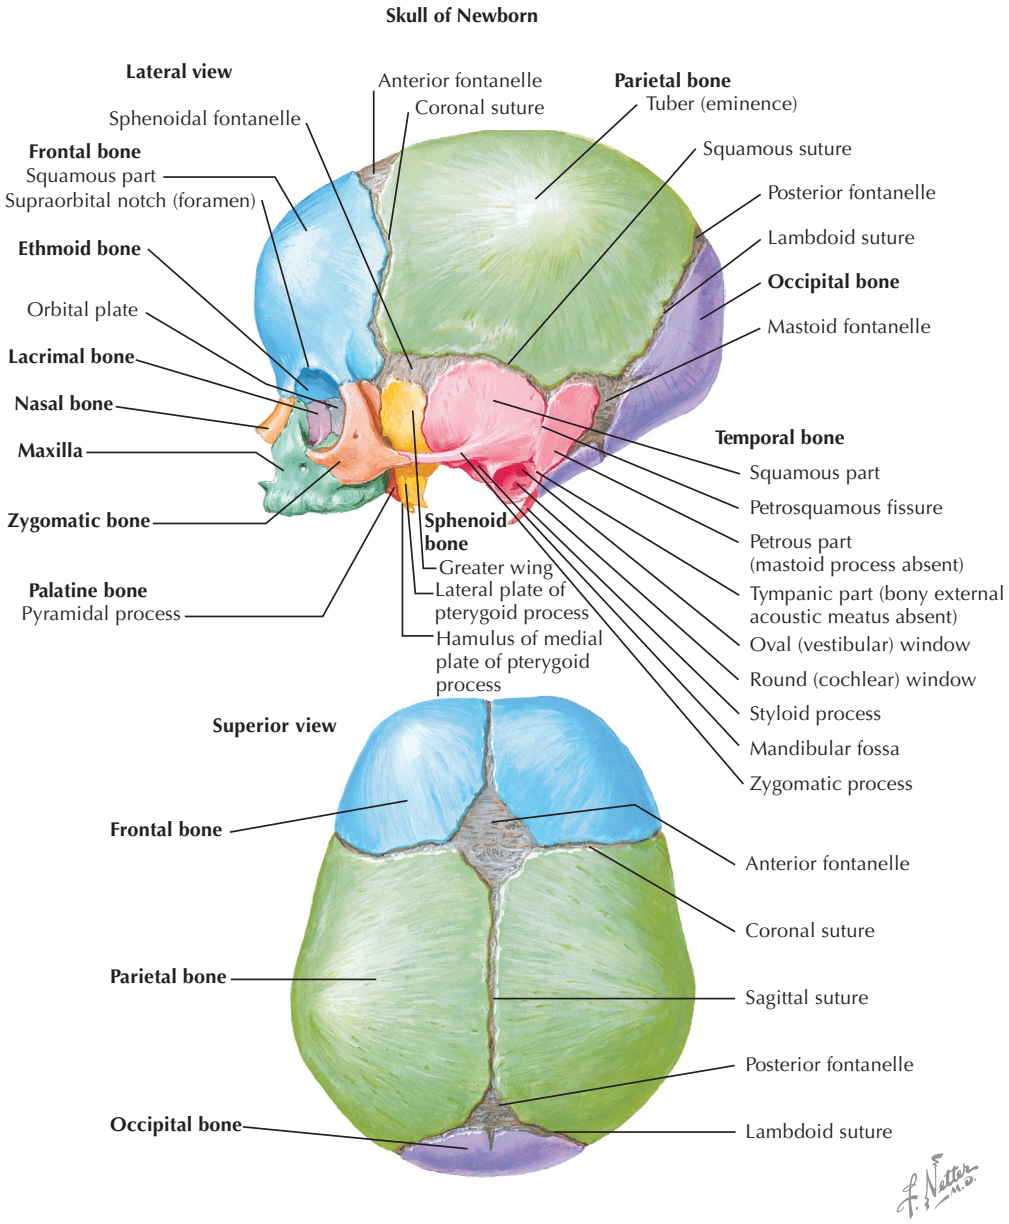
Skull

The *skull* is formed from the *lateral plate mesoderm* (the neck region), the *paraxial mesoderm,* and the neural crest (Fig. 4-1). The bony skull is formed by one of two mechanisms: *intramembranous ossification* or *endochondral ossification*. Skull development is divided into two parts: the *viscerocranium* and the *neurocranium*. The viscerocranium forms the bones of the face, whereas the neurocranium forms the bones of the cranial base and the cranial vault. The neurocranium can be divided into the membranous neurocranium and the cartilaginous neurocranium. The anterior fontanel (bregma) has a wide range of expected closure between 4 and 26 months of age. The posterior fontanel (lambda) generally closes between 1 and 2 months of age.

From the *first pharyngeal pouch* are formed the maxillary process, the mandibular process, and the second pharyngeal arch. Many bones are derived from the maxillary arch, including the maxilla, the temporal bones, the zygoma, the palatine bone, the lacrimal bone, the vomer, the nasal bones, and the inferior nasal concha. The *mandibular process* forms the mandible, the sphenomandibular ligament, the malleus, and the incus. From the *second pharyngeal arch* are



• **Figure 4-1** Illustrations of the development of the skull. *From* www.netterimages.com. *© Elsevier Inc. All rights reserved.*



• **Figure 4-1, cont'd**

formed the styloid process, the stapes, the hyoid bone, and the stylohyoid ligament.

Face

The *face* is formed mainly from the *neural crest,* which makes three "swellings" that surround the stomodeum (Fig. 4-2). The three swellings are the *frontonasal prominence,* the *maxillary prominence* (from the first pharyngeal arch), and the *mandibular prominence* (from the first pharyngeal arch).

Lateral to the frontonasal prominence, there are two areas of ectoderm that form the *nasal placodes,* which invaginate in the center to form the *nasal pits.* The placodes that invaginate create ridges of tissues on either side of the pits. The ridges are called the *lateral nasal prominence* and the *medial nasal prominence*. The fusion of the medial nasal prominence at the midline results in the formation of the *intermaxillary segment*.

Palate

The *palate* is formed by the *primary palate* (intermaxillary segment) and the *secondary palate* (protrusions from the lateral prominences) (Fig. 4-3). The *intermaxillary segment* (primary palate) is the initial portion of the palate to develop. It contains the central and lateral incisors. Swellings of the *maxillary prominence* form shelves that project medially but that are separated by the tongue. When the tongue no longer occupies the space between the palatal shelves, these processes fuse together to form the secondary palate. The primary and secondary palatal tissues all meet at the *incisal foramen*. The primary and secondary palates and the nasal septum fuse to form the *definitive palate*.

Syndromes and Anomalies that Include Dentofacial Deformities

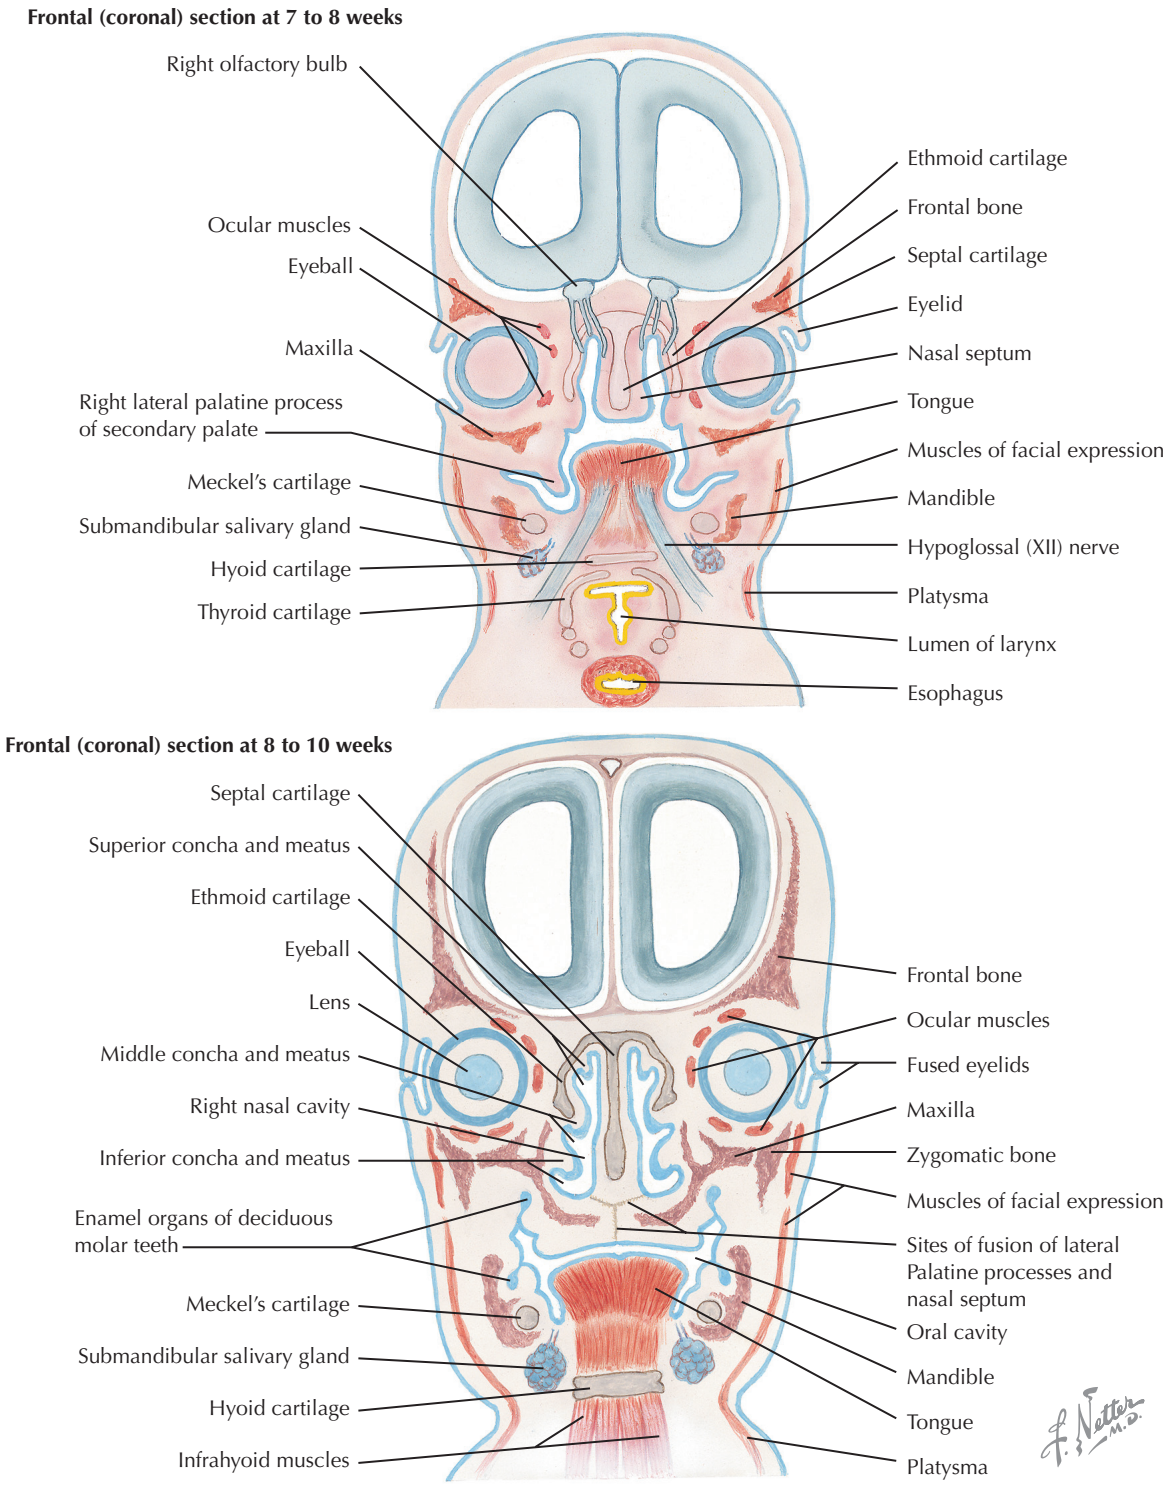
Many of the syndromes and anomalies that involve the cranio-orbito-zygomatic (upper face) region also affect the maxillomandibular (lower face) location.[1,20,124] These conditions may involve any of the tissue components, including the skin, the muscles, the nerves, the fat, the vessels, the bone, the teeth, the cartilage, and the associated viscera (i.e., brain, ears, eyes, salivary glands, sinuses). *Known syndromes and anomalies* comprise only a small proportion of the dentofacial deformity group (see Chapters 27 through 31).[19] These conditions can be further subdivided according to etiology or tissue of origin.

Deficiencies of Midline Tissue Structures

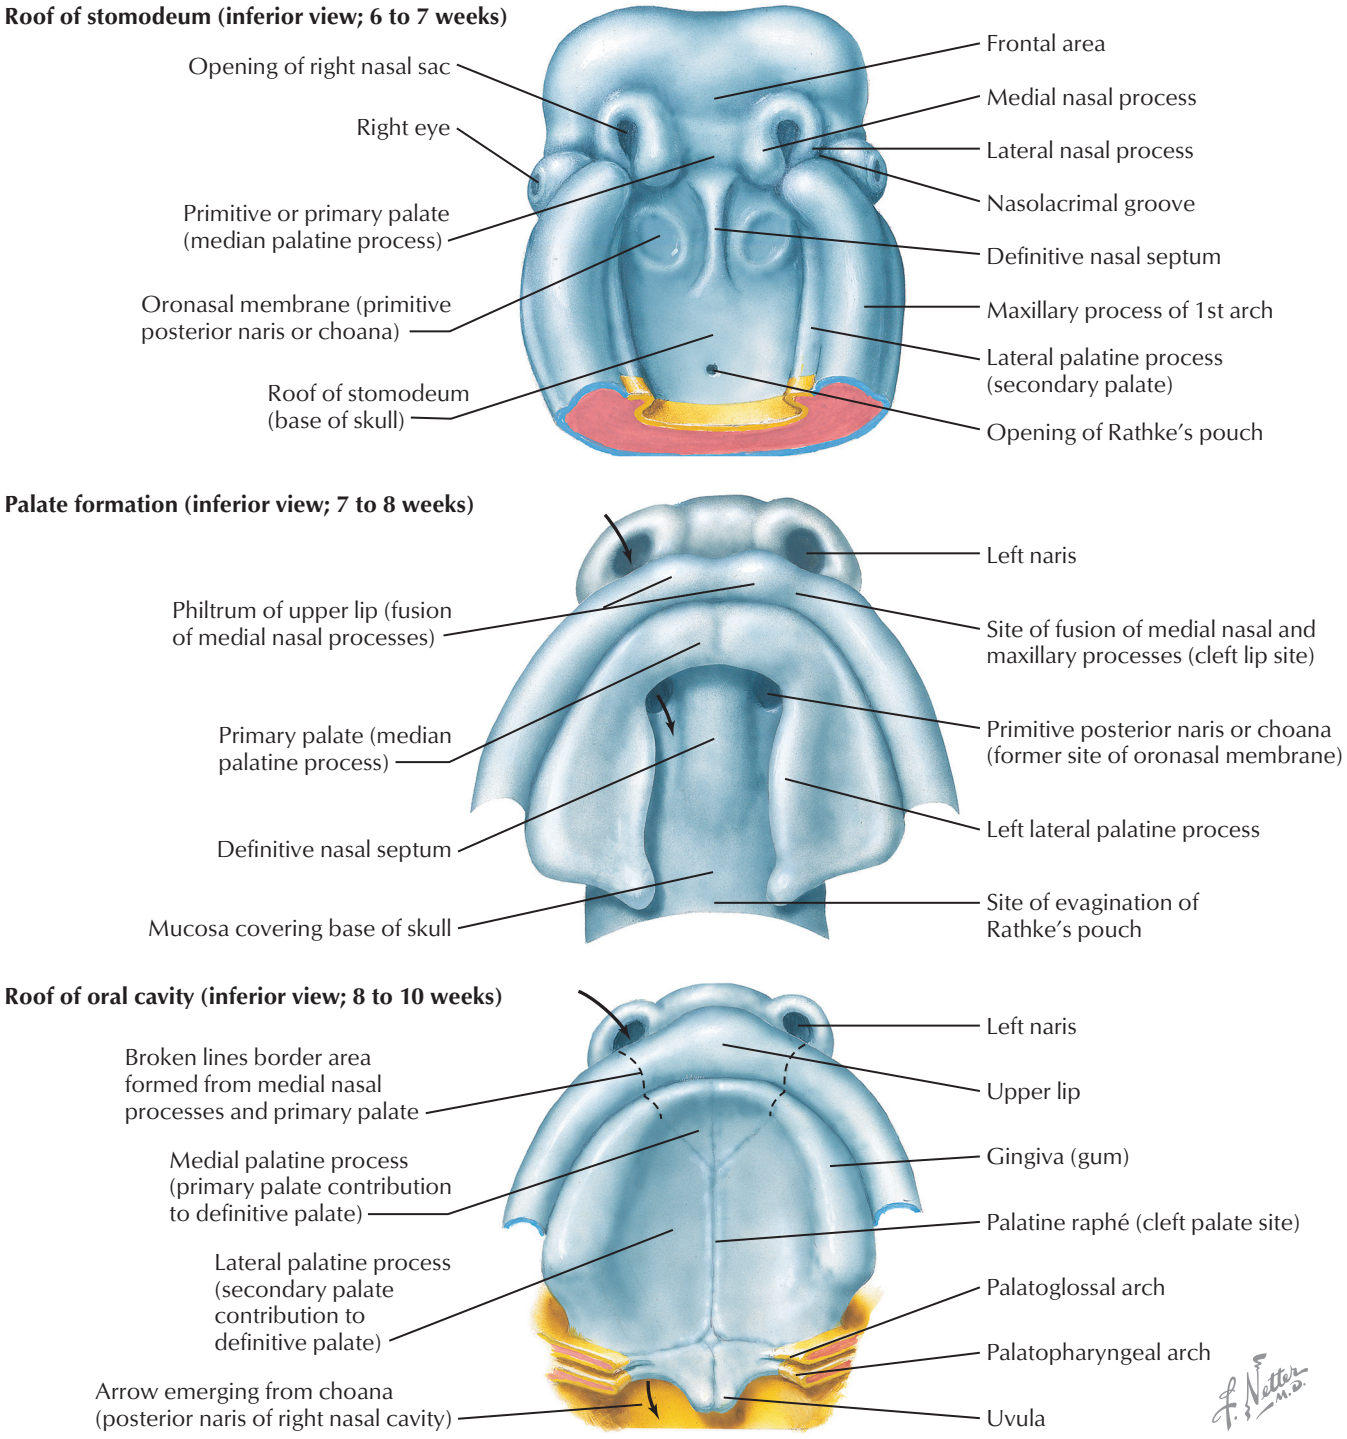
Holoprosencephalies involve variable deficiencies of midline tissues. These structural deficiencies have been documented to occur early during embryologic development.[16,18,23,27] They may range from severe brain anomalies to simple absence or hypoplasia of the corpus callosum. Severe facial anomalies such as cyclopia, ethmocephaly, and cebocephaly are always associated with severe holoprosencephaly, and they are incompatible with life. This can also be true of premaxillary agenesis; however, in some instances, patients may survive for several months or even years. There are reported cases of premaxillary agenesis with normal head circumference and no brain abnormalities (i.e., without holoprosencephaly), although these patients sometimes have mild mental deficiencies. Syntelencephaly (the absence or hypoplasia of the corpus callosum or absent or hypoplastic olfactory tracts and bulbs) is compatible with life and should thus be treated. Associated facial anomalies include retinal colobomas, cleft lip, cleft palate, single maxillary central incisor, and midface deficiencies. Holoprosencephaly has multiple causes and includes many chromosomal types, many monogenetic disorders, and at least three teratogens.

Deficiencies and Anomalies of Neural Crest Origin

Most of the tissues of the face, including the muscular and skeletal components, are derived from the *mesoderm*. Interestingly, throughout the rest of the body, these components (i.e., muscle and skeleton) are derived from an *ectodermal* origin.[19] The facial *mesodermal elements* develop from the neural crest and then migrate downward beside the neural tube and laterally under the surface ectoderm. When the *neural crest cells* have completed migration to their specific location, then facial development is dominated by specific growth centers, the formation of visceral structures (e.g., brain, eyes, sinuses), and the differentiation of the tissue layers. *Facial anomalies of neural crest origin* are thought to arise when the neuroepithelium has apoptosis (i.e., the cells die).[25] This results in less neuroepithelium to migrate through into the facial locations and to ultimately



• **Figure 4-3** Illustrations of the development of the palate. *From* www.netterimages.com. *© Elsevier Inc. All rights reserved.*

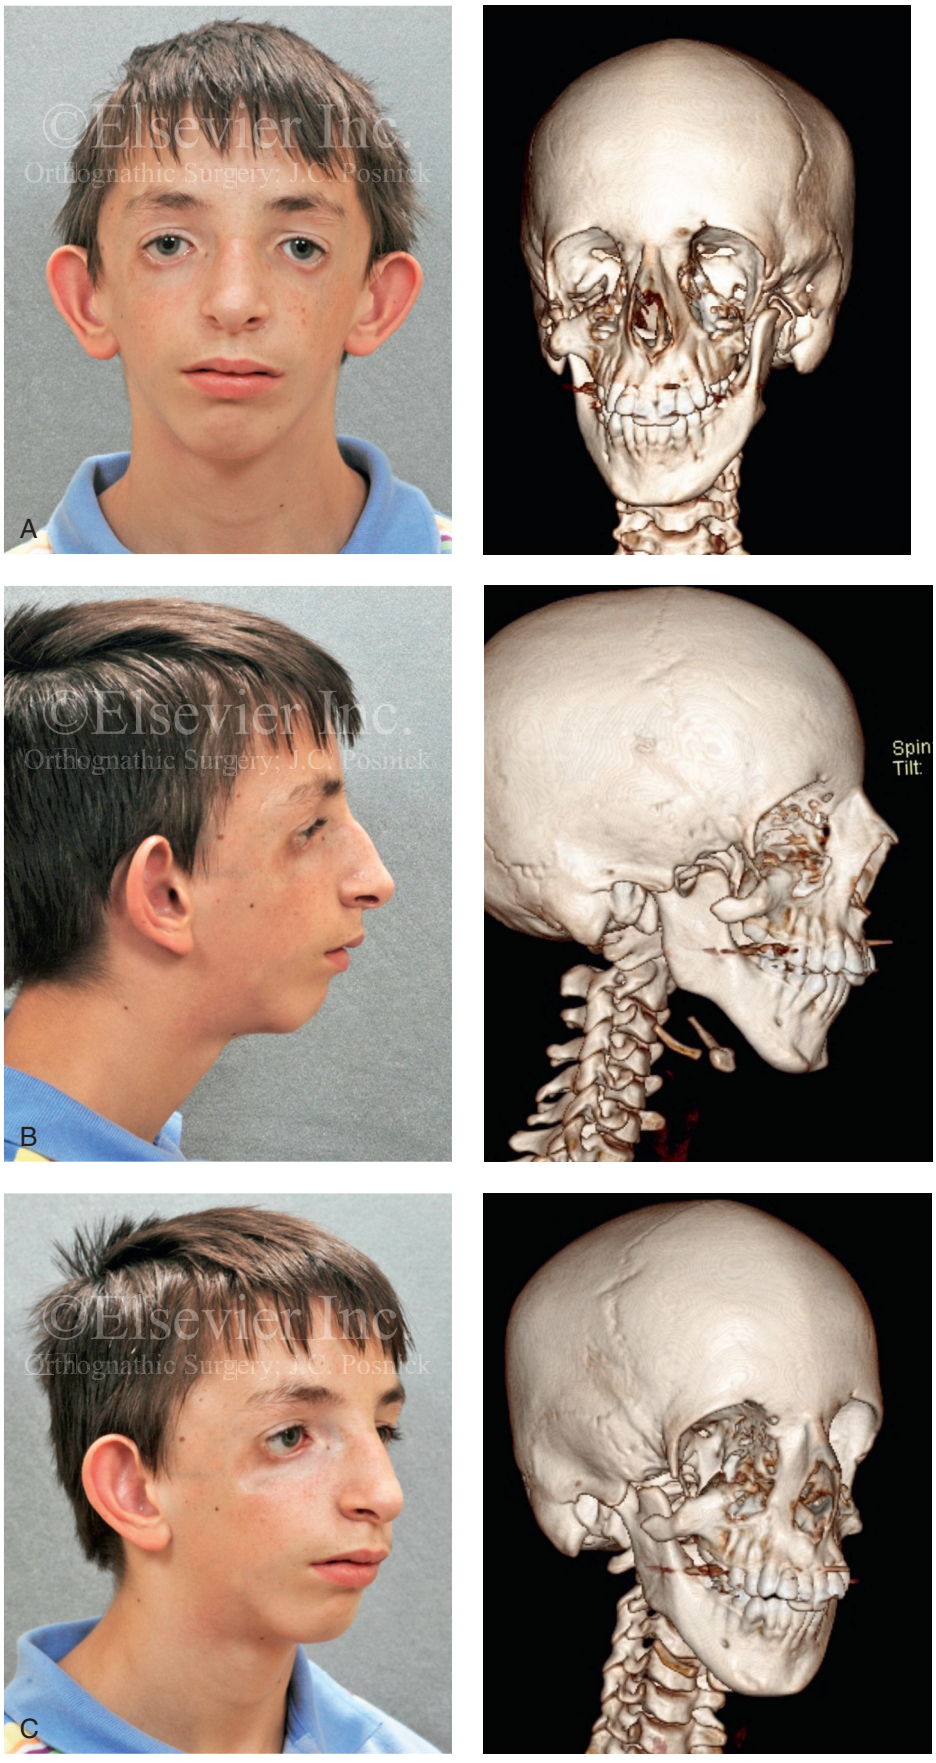


• **Figure 4-3, cont'd**

differentiate. Current knowledge of Treacher Collins syndrome indicates that this is not a migration problem but simply a lack of cells to migrate (Figs. 4-4 and 4-5).

Teratogens that are known to result in head and neck (neural crest) congenital anomalies include cytomegalovirus (microcephaly, hydrocephaly, microophthalmia); Dilantin (cleft lip and palate); vitamin D excess (premature suture closure); Valium (cleft lip and palate); Rubella virus (microophthalmia, cataracts, deafness); and thalidomide (variations of hemifacial microsomia and Treacher Collins syndrome). Despite these known relationships, teratogenic agents are not the most frequent causes of these syndromes.[1]

The *branchial arch syndromes* are neural crest anomalies that comprise an etiologically heterogeneous group of disorders.[14] They account for only a small percentage of the patients who present to the surgeon or orthodontist in need of jaw reconstruction. The best known of these are



• **Figure 4-4** An 11-year-old boy who was born with Treacher Collins syndrome has typical malformations of the soft tissues and the skeletal structures within the first and second branchial arches on both sides. There is significant hypoplasia of each zygomatic complex, the orbits, and the maxillomandibular structures (Kaban type II-A mandible). The soft tissues of the adnexal region are deficient. The external ears are malformed, but all parts are present. The central part of the face is fully formed. **A,** Frontal facial and computed tomography scan views. **B,** Profile facial and computed tomography scan views. **C,** Oblique facial and computed tomography scan views.

• **Figure 4-5** This mother and daughter demonstrate the extent of variation of expression of Treacher Collins syndrome within a family. The mother was not aware that she carried the Treacher Collins gene until after the birth of her daughter. *From Posnick JC: Treacher Collins syndrome: perspectives in evaluation and treatment.* J Oral Maxillofac Surg *55:1120–1133, 1997.*

hemifacial microsomia, its variant Goldenhar syndrome, and Treacher Collins syndrome.[14] *Hemifacial microsomia* affects aural, zygomatic, and mandibular growth at a minimum (Fig. 4-6). The disorder may be mild or severe, and it is generally limited to one side of the face. However, bilateral involvement, with more severe expression on one side, is also known to occur. *Goldenhar syndrome,* which is a variant of hemifacial microsomia, also includes epibulbar dermoids and vertebral anomalies. Involvement is often but not always limited to the face. There may be cardiac, renal, skeletal, and central nervous system anomalies (see Chapter 28). At a minimum, patients with *Treacher Collins syndrome* demonstrate the physical findings of bilateral zygomatic hypoplasia, down-slanting palpebral fissures, malformed ears, and micrognathia (see Chapter 27). Inheritance occurs in an autosomal-dominant fashion, and expressivity varies (see Figs. 4-4 and 4-5). The syndrome maps to 5q32-q33.1, and mutations in the *TCOF1* gene are of the nonsense, insertion, deletion, or splice-site types.[14,30,139]

Clefting of the Lip and Palate

The most prevalent congenital defect of dentofacial development is *clefting of the lip, the palate, or both* (Figures 4-7 through 4-19). This condition occurs in approximately 1 in 1000 whites, 1 in 500 Asians, and 1 in 2000 blacks.[27] The etiology of clefts is often complex and multifactorial. Evidence supports the view that genetic factors are associated with orofacial clefting.[37] In twins with cleft lips and palates, concordance is far greater among monozygotic twins (40%) as compared with dizygotic twins (4.2%). In twins with isolated cleft palate, concordance is also higher among monozygotic twins (35%) as compared with dizygotic twins (7.8%).[138] Nevertheless, orofacial clefting is heterogeneous and variable, and it is likely determined by a number of major genes, minor genes, environmental factors, and a developmental threshold.[37] Some syndromes associated with clefting in which specific gene mutations have been identified include van der Woude syndrome *(IRF6)*, popliteal pterygium syndrome *(IRF6)*, autosomal-recessive cleft palate/ectodermal dysplasia *(PVRL1)*, hypodontia/clefting *(MSX1)*, Hay-Wells syndrome *(TP63)*, and cleft palate/ankyloglossia *(TBX22)*. These mutations explain only about 5% of clefting cases, with an additional 10% to 15% of cases explained by variations involving the *IRF6* gene.[110] Although orofacial clefting is caused by a malformation, the development of secondary deformities of the jaws after birth is well known (see Chapters 32, 33, and 34). For the most part, maxillary hypoplasia in patients with orofacial clefts is felt to be the result of palate surgical interventions carried out during infancy and early childhood and not from the primary congenital anomaly. Although van der Woude and Stickler are just 2 of more than 100 clefting syndromes, they demonstrate the importance of having an awareness of associated anomalies to assist with family counseling and to achieve effective reconstruction.

Van der Woude Syndrome

In 1845, Demarquay was the first to report the occurrence of congenital sinuses of the lower lip in combination with cleft lip and palate; this condition became known as *van der Woude syndrome*. This syndrome occurs in roughly 1% to 2% of patients with lip and palatal clefts. Van der Woude syndrome has an autosomal-dominant inheritance pattern;

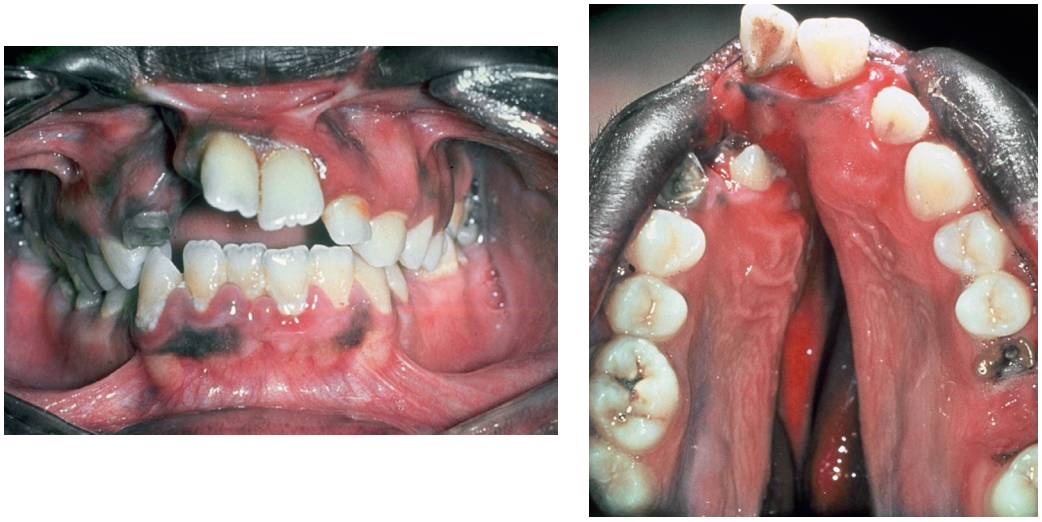
• **Figure 4-14** A child born with a complete cleft of the right lip and palate and incomplete clefting of the left lip. He is shown **A,** before and then **B,** at 2 and **C,** 8 years after primary lip and palate repair. The last photo was taken just before mixed dentition bone grafting.

• **Figure 4-15 A,** A child born with complete clefting of the secondary palate (i.e., incisal foramen through the uvula) is shown. **B,** An adult born with a complete unilateral cleft lip and palate is also shown. He underwent lip repair during childhood, but the cleft palate was neglected. Note the severe septal deviation that obstructs the right nasal valve.



• **Figure 4-16** A teenage boy from Jamaica who was born with a bilateral cleft lip and a unilateral cleft of the alveolar ridge and palate. He underwent rudimentary lip repair as a child. The unrepaired clefted alveolus and palatal anatomy are shown. Note the normal growth parameters of the upper jaw when the palate is unrepaired. With a lack of continuity of the alveolar ridge, there has been typical distorted growth of the maxilla.

• **Figure 4-17** A woman who was born with bilateral cleft lip and palate and pitting of the lower (central) lip. At the time of her pregnancy, an ultrasound confirmed twins, one of which was suspected of having bilateral cleft lip and palate and the other of having unilateral cleft lip and palate. This was documented at the time of delivery. **A,** A family with van der Woude syndrome, including a mother with a repaired bilateral cleft lip and palate and newborn twins. **B,** Twin A with bilateral cleft lip and palate. **C,** Twin B with unilateral cleft lip and palate.

• **Figure 4-18** A 16-year-old boy who was born with Stickler syndrome (type II collagen mutation). At the time of birth, Pierre Robin sequence was appreciated. The patient underwent repair of the cleft palate before he was 1 year old. He had positive eye findings, and he required the treatment of a retinal detachment during his teenage years. A small cataract is being followed. He arrived for the evaluation of a jaw deformity and malocclusion characterized by maxillomandibular deficiency with anterior open-bite malocclusion. This was combined with chronic obstructive nasal breathing and a long face growth pattern. Attempted growth modification and camouflage orthodontics earlier during life were ineffective. There was generalized root deficiency throughout the maxillary and mandibular dentition, likely as a result of the collagenopathy. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

Continued

• **Figure 4-18, cont'd** The patient agreed to an orthodontic and surgical approach. Further orthodontic (dental) decompensation was cautiously carried out as a result of the compromised periodontal apparatus. The procedures included maxillary Le Fort I osteotomy (vertical intrusion, horizontal advancement, counterclockwise rotation, and arch expansion); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical shortening and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **C,** Oblique facial views before and after treatment. **D,** Profile views before and after treatment.

Prior to retreatment

After surgery

• **Figure 4-18, cont'd H,** Panorex radiographs before and after treatment that demonstrate generalized limited root formation. The right maxillary first molar was lost 5 years earlier as a result of limited roots. The right maxillary first molar was lost 1½ years after surgery as a result of limited root support; the right mandibular first molar will likely be lost to similar pathology. Periodontal evaluation and treatment are ongoing. Future plans are for the placement of dental implants in the right posterior maxilla and mandible.

• **Figure 4-19** A child born with Robin sequence, which consists of retrognathia with glossoptosis, clefting of the secondary palate, and a degree of respiratory distress. **A,** Frontal facial and intraoral views demonstrating clefting of the secondary palate. **B,** Profile facial view indicating retrognathia. Computed tomography scan demonstrating retrognathia but with all of the components of the jaw present. For this child, the small mandible is the result of deforming forces during fetal development rather than the result of a malformation. Catch-up growth of the mandible is anticipated during childhood. **C,** Profile and occlusal views when the patient was 9 years old, with expected catch-up growth.

it has approximately 90% penetrance, and it is variably expressed (see Fig. 4-17). Manifestations of the syndrome outside of the oral and facial regions are unusual. Generally, the pits are characterized as depressions that are observed on the vermilion border of the lower lip; they are usually bilateral and symmetrically placed, although an asymmetrical pit or single central pit may occur. Roughly 33% of patients with van der Woude syndrome have pits without clefting, 33% have pits with cleft lip and palate, and 33% have lip pits with isolated cleft palate or submucous cleft palate. Approximately 10% of those individuals with van der Woude syndrome do not exhibit lip pits.

Stickler Syndrome

In 1967, Stickler and Pugh were the first to describe a series of patients who had a combination of eye findings, hearing loss, isolated cleft palate, a Marfanoid habitus, and long-bone changes.[1] It is now known that *Stickler syndrome* is associated with basic defects in collagen. These collagenopathies include mutations on type II collagen and mutations in type XI collagen.[25] The inheritance pattern with this syndrome is autosomal dominant with variable expressivity. Cohen and others have reviewed the relationship between high myopia and clefting of the secondary palate and the other features of Stickler syndrome.[19] High myopia (i.e., 8 to 18 diopters) is found in 75% of patients by the time they are 5 years old. The eye findings are progressive, with vitreous and chorioretinal degeneration and retinal detachment observed in 70% of patients by the time they are 20 years old. Additional eye findings include astigmatism, cataracts, strabismus, and glaucoma. Individuals with Stickler syndrome may manifest any or all of a range of craniofacial findings, including mild to moderate midface hypoplasia, shallow orbits with eye proptosis, epicanthal folds, a flat nasal bridge, and submucous or full clefting of the secondary palate. Some affected individuals will have progressive degeneration of the dental roots and the associated periodontium. This is primarily due to the inborn error in collagen production, but it may be exacerbated by malocclusion (secondary trauma) and orthodontic manipulations (see Fig. 4-18). Progressive neurosensory high-tone hearing loss has been reported in 80% of patients. Some patients have a Marfanoid body habitus, whereas others have short stature. There may be progressive early joint degeneration by the mid-adult years. Any newborn who is found to have Robin sequence should undergo an initial genetic and ophthalmologic assessment to rule out Stickler syndrome.

Robin Sequence

Robin sequence is commonly defined as cleft palate, micrognathia, and glossoptosis (see Fig. 4-19). This sequence of events can occur as a result of a variety of etiologic and pathogenetic conditions, and it involves a wide spectrum of phenotypes. The distinction must be made between a malformed mandible (micrognathia) and a deformed mandible that is simply retrognathic. The malformed mandible (i.e., Treacher Collins syndrome) may also be missing parts or sections of the jaw (i.e., Kaban types IIB and III) and cannot be expected to "grow out" and self-correct. This is different from a deformed mandible (i.e., retrognathic at birth) caused by fetal malpositioning, which can be expected to "grow out" and become relatively normal. The newborn's respiratory compromise that occurs with Robin sequence will vary according to the child's physical findings, and treatment should proceed accordingly. For example, with spondyloepiphyseal dysplasia congenita, the causes of respiratory compromise include a small and mechanically abnormal chest, tracheobronchial malacia, and central apnea as a result of cervical or medullary compression caused by cervical instability.[47] This will require a different level of airway management as compared with an isolated retrognathic mandible, which is simply deformed as a result of intrauterine compression. If the deformed (retrognathic) mandible is present at birth, it is expected to "catch up" during growth and basically to self-correct. For these infants, mandibular osteotomies with advancement carried out during childhood should be avoided.

Achondroplasia

Achondroplasia is the most common condition associated with severe disproportionate short stature.[22] The cause of this condition is the failure during development of the primary growth cartilages of the limbs and the cranial base. This results in short arms and legs as well as a characteristic midface deficiency or deformity that is most visually notable at the nasofrontal process.

Most affected individuals do well but attain a final height of only approximately 4 feet. The condition is known to be caused by mutations on the *FGFR3* (fibroblast growth factor receptor 3) gene.[22] Eighty percent of reported cases are sporadic, whereas 20% are familial. Although craniosynostosis is not a typical feature, three cases with craniosynostosis have been reported.

Premature Suture Closure of the Cranial Vault and Skull Base

The flat bones of the cranial vault develop from mesenchymal condensations over the developing brain (see Fig. 4-1). These bones grow primarily via the apposition of bone at their edges. The regions in which the cranial bony edges collide are called *sutures.* In addition to appositional growth at the edges (i.e., suture growth), cranial vault development also occurs through the process of remodeling (i.e., resorption and deposition).[17] Continued separation of the sutures during the process of the apposition of bone at the edges is also important to the normal growth of the bones of the cranial base and the midface.

Synostosis is a condition of premature fusion (i.e., the arrest of appositional growth at the bone edges) that occurs before the associated visceral structures (e.g., brain, eyes) complete growth.[17] When this happens, there is distortion

or deformity of the shape of the affected bones and possible compression of the underlying visceral structures (i.e., the brain). Premature closure of the cranial vault sutures (craniosynostosis) that do not extend into the cranial base will have minimal effects on the maxillofacial form (e.g., metopic, unilateral coronal, and sagittal suture synostosis; Figures 4-20, 4-21, and 4-22). However, prematurely fused cranial vault sutures that extend into the cranial base will also affect midfacial growth and development (e.g., Crouzon, Apert, and Pfeiffer syndrome; Figures 4-23 through 4-26; see Chapter 30).

Overgrowth Syndromes and Anomalies

Acromegaly is caused by an anterior pituitary tumor that secretes excessive growth hormone after the normal completion of growth.[21] The response of specific growth centers to abnormal serum levels of growth hormone is the overdevelopment of the hands, the feet, the supraorbital ridges, and the mandible. When there is excessive mandibular growth, the position of the teeth within the bone and the occlusion are also effected. An enlarged sella turcica (i.e., the resorption of bone in response to pituitary tumor expansion) can be seen on a lateral cephalometric radiograph or a computed tomography scan (Fig. 4-27). Excess growth hormone causes the proliferation of the condylar cartilage of the mandible, thereby resulting in the bilateral symmetric forward projection of the jaw. This overgrowth continues until the serum growth hormone levels return to normal. Unfortunately, the resultant skeletal deformities persist. Other examples of maxillomandibular overgrowth include hemifacial hypertrophy (see Chapter 31), hemimandibular hyperplasia, and hemimandibular elongation (see Chapter 22).

Hereditary Tendencies in the Development of Dentofacial Deformities

Jaw deformities are thought to be more common among individuals with genetic backgrounds that are crosses between different racial and ethnic groups as compared with those from isolated human populations.[10,32,40,57,59,60,62,83,85,86,91,93,108] It has been documented that crossing different breeds of dogs and other mammals can result in striking dentofacial deformities, particularly mandibular prognathism that resembles the human variant.[82,117,119] Harris and Johnson examined the longitudinal records from the Bolton Brush Growth Study and concluded that the heritability of maxillomandibular characteristics is relatively high[48] (Figures 4-28, 4-29, and 4-30). It is assumed that approximately one third of children who present with a severe Class III malocclusion will have a parent with the same problem and that one sixth of these children will have an affected sibling.[73] Interestingly, a short face growth pattern with a deep-bite malocclusion is found more frequently in whites (see Chapter 23). Bimaxillary dento-alveolar protrusion with anterior open-bite malocclusion is more prevalent among blacks (see Chapter 24).[112]

The Class III skeletal pattern of maxillary deficiency with relative mandibular excess is known to be more frequent in certain races.[2,73,84,123,139] Incidence rates of Class III malocclusion of as high as 13% have been reported in specific regions of Asia.[136] Lew and colleagues examined occlusal parameters in 1050 Chinese school children between the ages of 12 and 14 years. They found an incidence of 12.6% for Class III malocclusion, 58.8% for Class I malocclusion, and 21.5% for Class II malocclusion.[67] Samman and colleagues investigated 300 Chinese individuals residing in Hong Kong who were known to have a dentofacial deformity and who had been referred to an "orthognathic surgery clinic." After excluding those individuals with cleft lip and palate, 222 study patients remained. Forty-seven percent of these individuals (n = 104) were found to have a Class III skeletal growth pattern.[106]

Several of the common maxillomandibular disharmonies are known to result from environmental influences (see Chapters 10 and 21). The dental position in each arch and the resulting occlusal variations are felt to have an even greater environmental component.[3,11,29,41,64,92] For example,

• **Figure 4-27** A middle-aged woman who presented for the orthodontic evaluation of a progressive malocclusion. She had a normal occlusion, average facial features, and no distortions of the extremities earlier during life. Gradually, over the prior 5 years, malocclusion and changes in facial and extremity morphology had occurred. At presentation to the orthodontist, standard records were taken (lateral cephalometric and Panorex radiographs and dental models). The patient was then seen for surgical evaluation. A review of the lateral cephalometric radiograph showed an enlarged sella turcica. An endocrinology consult confirmed the diagnosis of acromegaly. Appropriate treatment was undertaken without further worsening of the facial or extremity deformities. **A,** Facial and occlusal views at presentation indicate growth hormone changes. **B,** Profile and lateral cephalometric views at presentation. dento-alveolar morphology is commonly affected by thumb sucking and other para-oral habits (i.e., environmental influences; Figures 4-31 and 4-32). The more severe the dentofacial deformity, the more likely that inheritance plays at least a partial role. Maxillary deficiency with relative mandibular excess (i.e., a Class III skeletal pattern) and maxillomandibular deficiency (i.e., the short face growth pattern) are both thought to have a significant hereditary component.[31,36,58,79,116,120,137]

Environmental and Neuromotor Effects on Skeletal Growth

The *mandible* can be viewed as a somewhat malleable block of hard tissue that is adjacent to the skull base. It is separated from the skull by working temporomandibular joints. It houses the inferior alveolar neurovascular bundle, and it provides a matrix for the formation, eruption, and eventual alignment of the teeth. Muscular activity in the head and neck can directly affect skeletal growth through one of the following mechanisms: 1) hyperactivity of muscles at the point of attachment may cause excessive skeletal remodeling or contour deformities (as discussed later in this chapter) 2) hypoactivity of the masticatory muscles may cause distortions of the normal skeletal growth (i.e., long face growth pattern; Fig. 4-33) and 3) hyperactivity of specific muscles such as the sternocleidomastoid (i.e., torticollis) may result in the deformation of the growing bones (i.e., cranial vault, orbit, and zygoma; Fig. 4-34).[71]

Muscle and Soft-Tissue Effects on Skeletal Growth

Experimental animal research and clinical observational studies confirm that the influences of the *mandibular rest posture,* the *neck rest posture,* and the *tongue and lip rest position* of the affected individual's eventual facial morphology are real and more important than the effects of intermittent muscle contracture (see Chapters 8 and 10).[128-130] It is also known that functional stresses that are placed on the skeleton will increase bone density.[113,114,118] A corollary is that, during periods of inactivity (e.g., mandibular and neck rest posture), skeletal demineralization occurs.

Erupting teeth carry alveolar bone with them. Therefore, forces that counteract the normal eruption of teeth can shape the dental arches and the alveolar processes of both the maxilla and the mandible.[5,101-105,107,109,111,126,140] Experimental studies confirm that pressure against the active eruption of the teeth that is maintained for 4 to 6 hours can affect tooth movement and initiate bone remodeling (see Chapter 5). Habits such as *finger or thumb sucking,* which apply consistent pressure against the teeth, can have the

same effect on the shaping of the dental arches (see Figs. 4-31 and 4-32). It seems as though the intensity (i.e., the amount of force) against the teeth is less important than the duration (i.e., the number of hours per day) with regard to causing this effect.

It has been confirmed that the *postural position of the tongue at rest* (e.g., the mandible open with the constant protrusion of the tongue) rather than where the tongue is placed during function (e.g., a tongue-thrust swallowing habit) is most important for determining the eventual position of the teeth and the morphology of the dento-alveolar complex.[61,121] The intermittent forces that are generated against the teeth during chewing, swallowing, and speaking are documented to be more than heavy enough to produce tooth movement. However, during these normal functions, the force is not maintained long enough at any point in time to have an appreciable effect on the position of the teeth or the morphology of the bone.[35] Even repetitive intermittent "abnormal" tongue and lip contraction with resulting pressure on the teeth during swallowing and speaking (i.e., tongue thrusting)—despite their frequency—do not sum up to the number of hours of force required to produce a pathologic effect. By contrast, even very light forces sustained for a long duration (i.e., the tonic contracture of masticatory muscles to maintain mandibular posture) can affect both the path of tooth eruption and jaw development.[8,94]

It is known that muscles of different size and force that attach to the mandible at specific locations will result in characteristic ridges and contours (e.g., gonial angles, coronoid process, genial tubercle).[12,13] For patients with the condition known as *masseteric muscle hypertrophy*, there is excess bone proliferation at the masseter muscle's point of attachment along the inferior border of the mandible (i.e., the gonial angle ridge) in response to greater than average muscle forces.[43] By contrast, in patients with *muscular dystrophies* (i.e., hypotonic cerebral palsy, Moebius syndrome with cranial nerve palsy), the ramus may be short, and the gonial angles appear to be underdeveloped as a result of the limited muscle forces applied to these same regions.[100]

The lips, cheeks, and tongue contain muscles in their deep layers that exert varied pressures against the teeth and the alveolar process. They normally do so with a constant level of tone while at rest as well as during dynamic function. These light (tone) forces applied for a long duration are known to cause tooth movement and remodeling of the alveolar process. It is the "resting" postural pressures of these structures (i.e., lips, cheeks, tongue, and muscles), the presence of para-oral habits (i.e., thumb sucking, pencil biting; see Figs. 4-31 and 4-32), and the man-made and controlled orthodontic pressure that can exert the long duration of light force at the periodontal ligament that is required to move teeth.[55] When the difference between applied orthodontic forces and pressures of the tongue, cheek, and lips that counteract those forces applied to the periodontal ligament becomes great enough for sustained periods of time, tooth movement will occur. Another example of dental adaptation is seen when the constant strong force of the tongue is juxtaposed with intrinsic weaker bilabial (i.e., upper and lower lip) muscle tone forces.[135] This results in the predictable dental compensations (i.e., proclined maxillary and mandibular incisors) observed in patients with *bimaxillary dento-alveolar protrusion* (see Chapter 24). This also explains the consistent dental compensations that are typically observed in patients with specific developmental dentofacial deformities such as long face growth pattern (see Chapter 21 and Fig. 4-33) or isolated mandibular deficiency (see Chapter 19).[122]

Severe *scar contracture of the anterior neck and lower lip* soft tissues from a burn that occurred during childhood will also affect mandibular morphology. The soft-tissue contracture will distort ongoing skeletal growth and cause the mandible to be retrusive, with an obtuse angle. The chin region of the mandible will grow with increased vertical length and without sagittal prominence, and there will be an anterior open-bite malocclusion. This deformity and its surgical correction were first described by Simon Hullihen in 1849 (see Chapter 2 and Fig. 2-19).

When an *electric burn to an oral commissure* occurs during childhood and results in soft-tissue contracture with microsomia, the constant soft-tissue forces against the teeth will distort the shape of the dental arch and the alveolar process. There will be anterior dental crowding, tipping of the incisors, and malocclusion.

With the *congenital absence of part or most of the tongue,* there will be a characteristic V-shaped deficiency or dysmorphology of the mandibular dental arch (e.g., hypoglossia–hypodactylia syndrome; Fig. 4-35).[15] In the presence of a volumetrically enlarged tongue (e.g., vascular malformation, hemangioma, neurofibromatosis, Proteus syndrome, Beckwith-Wiedemann syndrome), there will be dento-alveolar effects that result in spaces between the teeth (Fig. 4-36). The lower anterior teeth will be flared, and the overall mandibular arch form will be enlarged. The important factor that causes these dental compensations and arch form deformities is the sustained and constant rest forces of the oversized tongue on the teeth and bone and not what the tongue does when it is in motion.

In the individual with a normal tongue volume and neuromotor capability, it is known that the rest position of the tongue in the mouth is primarily influenced by *respiratory factors*.[73] It is the rest position of the tongue that influences the pattern of dentofacial development rather than the position of the tongue during function.

In the presence of *chronic nasal obstruction,* a typical long face growth pattern with anterior open-bite malocclusion is likely to occur. In these circumstances, a speech therapist may have success with teaching the individual altered movement of the tongue for the formation of more accurate voluntary independent speech sounds.[90] However, unless the anterior open bite and the nasal obstruction are corrected, the myofunctional therapy will not allow the individual to reliably position his or her tongue, lips, teeth, and mandible for correct articulation during rapid conversational speech (see Chapter 8).

• **Figure 4-36** A 3-year-old child with a congenitally enlarged tongue is shown. The secondary effects on the oral cavity include a Class III anterior open-bite malocclusion and a lateral crossbite malocclusion.

In the skeletal Class III adult patient (i.e., a retrusive maxilla with relative mandibular excess) who undergoes successful orthognathic correction, a normal oral cavity volume and a normal occlusion are established. Interestingly, in most cases, the tongue position and lip posture will then naturally adapt to the new morphology.[80,81]

Clinical observation confirms that, when an individual with a longstanding dentofacial deformity undergoes successful reconstruction, it is generally not necessary to retrain the tongue with active myofunctional therapy. This only needs to occur under the following conditions: 1) when the tongue volume is truly excessive (e.g., vascular

malformation, neurofibromatosis) 2) when there is the presence of intrinsic neuromotor dysfunction (e.g., cerebral palsy) or 3) when the nasal airway remains obstructed and a failure of tongue adaptation is seen.[63]

Respiration Patterns and Their Effects on Skeletal Growth

Harvold conducted primate experiments that were designed to test hypotheses regarding *the relationship between nasal obstruction, mouth breathing, mandibular rest posture, tongue rest position, jaw growth, and dental malocclusion*.[49-54] He created an experimental model in growing rhesus monkeys *(Macaca mulatta)* to study these relationships. To do this, he completely obstructed the nasal passages in the study subjects with silicone nose plugs. The experiments showed that the monkeys adapt to total nasal obstruction in two different ways. Predominantly, the experimental animals maintained an open-mouth posture with tongue protrusion. Interestingly, some adapted to a forced oral airway by holding the upper and lower teeth close together but with wide lip separation. Nevertheless, both adaptive mandibular, tongue, and lip positioning patterns gradually resulted in maxillomandibular dysmorphology and dental malocclusion that was notably different from that seen in the control animals.

In the experimental animals, morphologic changes that occurred in the lips, tongue, dentition, jaws, and mandibular posture were documented by the research team through cephalometric measurements as well as through electromyographic and behavioral findings. Harvold's cephalometric findings documented changes in facial height (e.g., of the naso-palatal plane and the symphysis-palatal plane) and alterations in mandibular morphology.

As stated, a minority of animals adapted to the nasal airway blockage by holding their teeth together with wide lip separation (rather than maintaining an open-mouth posture with tongue protrusion) while still breathing through their mouths. This subgroup showed the least change in jaw morphology and dental alignment.

The observed morphologic and occlusal changes were most extreme when the mandible constantly remained open, with tongue protrusion (i.e., an open-mouth posture). The adaptive lowering of the mandible (with clockwise rotation) to achieve effective oral respiration was followed by secondary changes in the maxilla, including a downward displacement (i.e., vertical lengthening) of the alveolar process in conjunction with excess extrusion of the teeth. When molar (posterior) hypereruption was significantly greater than incisor hypereruption, an anterior open-bite malocclusion developed (Fig. 4-37).[127]

It became apparent to Harvold that the changes in mandibular shape and the direction of mandibular growth (i.e., clockwise rotation) observed in a majority of the experimental monkeys were dependent on the adaptive activity of the facial, tongue, jaw, and neck muscles in response to respiratory need. Interestingly, in Harvold's experimental animal model, there was no indication of abnormal bony apposition on the condyles in association with the forced oral respiratory pattern. The apposition of new bone on the condyles continued (in the usual way) independently of aberrant mandibular positioning or open-mouth posture.[107]

In review, the growing experimental animals studied by Harvold coped with nasal obstruction by changing neck, tongue, facial, and masticatory muscle tone, thereby resulting in alterations in mandibular posture and tongue position.[44,45,55] The animals typically did this in one of two different ways but always with the goal of maintaining adequate respiration. This resulted in varied but consistent secondary changes in the maxillomandibular morphology (i.e., developmental jaw deformity) and dental compensations (i.e., malocclusion). The measured lower facial height increase that occurred in the presence of a constant open-mouth posture was primarily the result of maxillary molar—and, to a lesser extent, incisor dental—hypereruption (e.g., long face growth pattern).

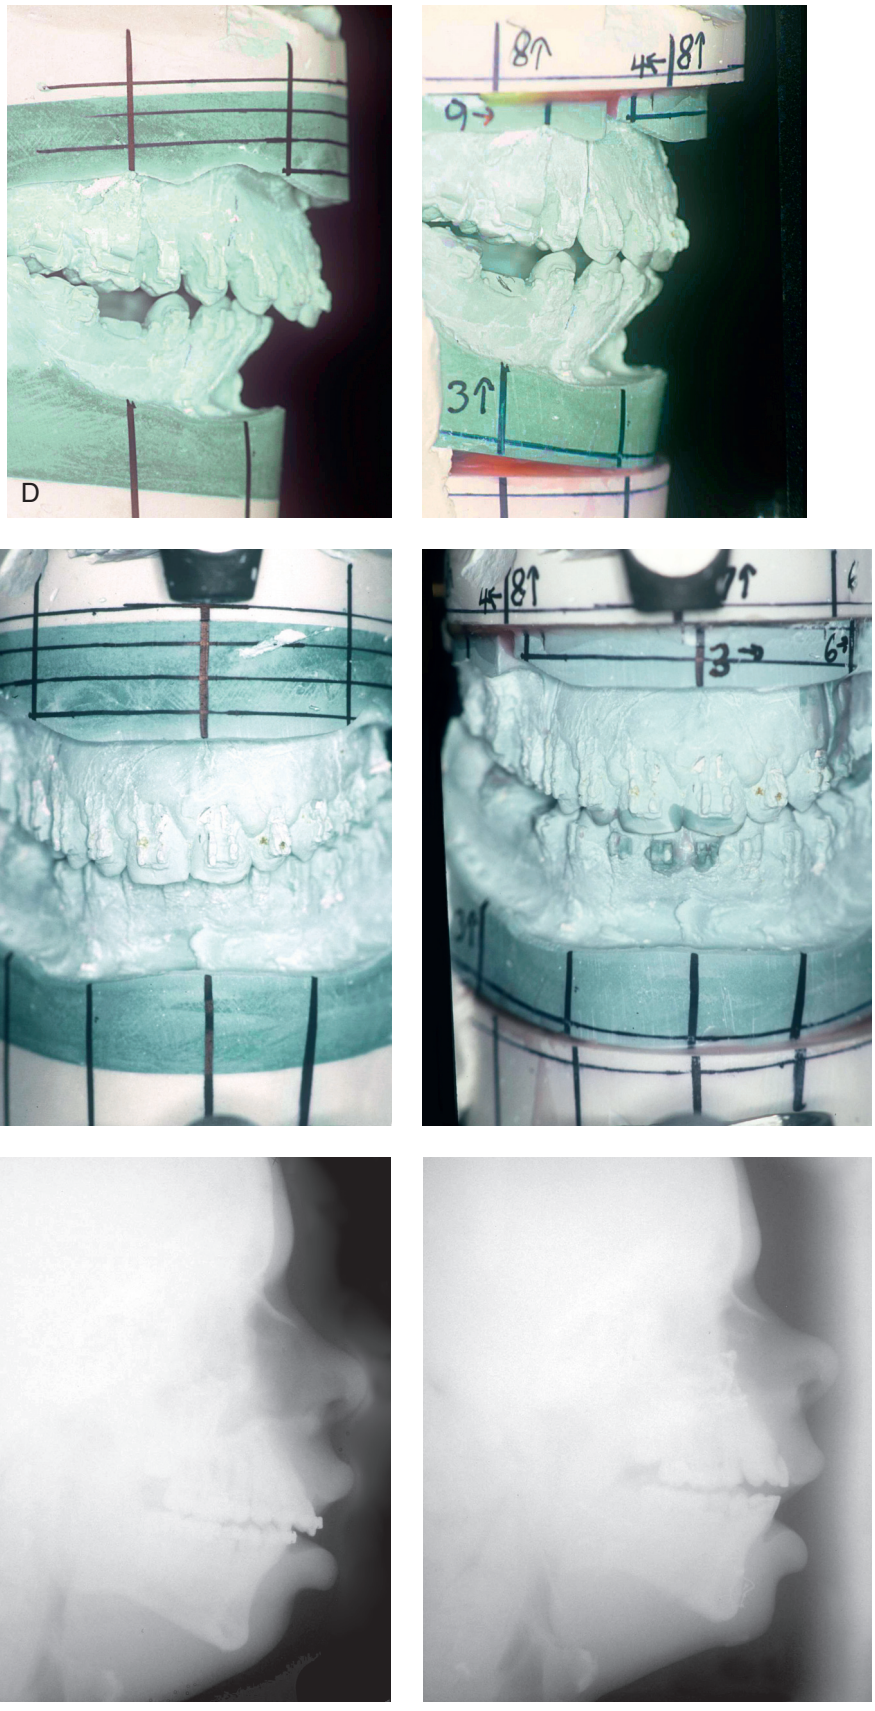
Harvold also reviewed the human observation studies of Linder-Aronson and colleagues and found that they paralleled his experimental animal research.[68-70,75-78] Their clinical research established that *nasal obstruction with forced mouth breathing* (i.e., open-mouth posture) in humans is frequently associated with maxillary dental extrusion, a steeper than normal mandibular plane, anterior open-bite malocclusion (i.e., the hypereruption of the molars is greater than that of the incisors), and increased lower anterior facial height. Similar to Harvold's experimental monkeys, growing humans may develop different neuromotor adaptations to cope with nasal obstruction and the need to maintain adequate respiration. The secondary skeletal and dental morphologic deviations will therefore vary, but they tend to occur in a predictable long face growth pattern (see Chapter 21).[39,125,133,134]

Humans with severe hypoplasia of the maxilla, a retropositioned palate and a restricted nasal airway, as are seen in patients with Crouzon or Apert syndrome, also become dependent on oral respiration (see Chapter 30).[4] With Crouzon or Apert syndrome, the individual's neck is often maintained in hyperextension with an open-mouth posture, the protrusion of the tongue, and the clockwise rotation of the mandible; this head and neck posture is compensatory to support respiration. During the day, this compensatory posture may be sufficient, but it becomes inadequate at night and results in obstructive sleep apnea (see Chapter 26).[4] When these compensatory adaptive changes occur during childhood, they contribute to additional secondary maxillomandibular skeletal dysmorphology with growth that further affects the occlusion (see Chapter 30).[7,33,115] This is an example of a congenital midface deformity that is further influenced by the environment.

Congenital Myopathies and Effects on Skeletal Growth

Individuals with *congenital myopathies* constitute a heterogeneous subgroup of patients with congenital

• **Figure 4-37** A 16-year-old with a nonprogressive congenital myopathy that resulted in a constant open-mouth posture. He developed a long face growth pattern that was characterized by severe maxillary vertical excess and protrusion, a retrusive mandible, and an Angle Class II malocclusion. He underwent a combined orthodontic and surgical approach. Orthodontic manipulation was limited as a result of hygiene control. The surgery included a maxillary Le Fort I osteotomy (vertical intrusion, first bicuspid extractions, and alveolar bone removal with premaxillary setback and cant correction) and sagittal split osteotomies of the mandible (clockwise rotation and asymmetric correction). **A,** Frontal views with smile before and after reconstruction. **B,** Oblique facial views before and after reconstruction. **C,** Occlusal views before and after reconstruction.



• **Figure 4-37, cont'd** **D** and **E,** Articulated dental casts that indicates analytic model planning. **F,** Lateral cephalometric radiographs before and after reconstruction.

neuromuscular disorders in which the pathology is attributable to defects in the muscle fibers rather than in the neurons. Congenital fiber-type disproportions are rare congenital myopathies that are considered slow or nonprogressive. Patients with these conditions, like those with other types of primary myopathies, will generally exhibit facial features that often result in what is described as a *"myopathic face."* The "myopathic face" has many similarities to the *"adenoid face"* that is seen in children with a blocked nasal airway due to enlarged adenoids and other intranasal obstructions, which result in an open-mouth posture. These abnormal human maxillomandibular growth patterns are also consistent with the findings reported by Harvold when rhesus monkeys were forced to maintain an open-mouth posture during jaw growth, as described previously in this chapter. The "myopathic face" findings described by Lehman and colleagues include characteristics of an increased lower anterior facial height, incompetent lips, a high-arched palate, and often anterior open-bite malocclusion (Figs. 4-37 and 4-38).[66] Clinical human and animal model studies confirm that these features are to be expected in the presence of an open-mouth posture during jaw growth, no matter what the cause. Although blocked nasal breathing is the most common cause of an open-mouth posture during growth, clearly congenital myopathies that also result in an open-mouth posture will produce the same facial dysmorphology.

Effects of Trauma on Skeletal Growth

Intrauterine compressive force against the developing face is a form of trauma that can lead to *deformations* of the craniofacial skeleton that are visually present at the time of birth. For example, when there is a decrease in the volume of amniotic fluid, the fetus' head is typically flexed tightly against his or her chest in utero. The compressive forces to the chin will prevent the mandible from achieving its full prenatal growth potential. The normally developing tongue is then forced to rest high in the mouth, thereby preventing approximation and fusion of the lateral maxillary processes. At the time of birth, clefting of the secondary palate is recognized. A pathologic process continues after birth, and this includes retrognathia, a cleft of the secondary palate, and varying degrees of respiratory distress as a result of the otherwise normal tongue resting superior and posterior in the mouth. This intrauterine deformation is responsible for approximately two thirds of those individuals with observed *Robin sequence* at the time of birth. Significant but incomplete catch-up mandibular growth is expected. In general, there will be sufficient mandibular growth in combination with an expected degree of maxillary growth inhibition from cleft palate repair during childhood that results in maxillomandibular harmony but at least mild horizontal deficiency and the clockwise rotation of both jaws. Individuals with these features are typically managed with orthodontics to achieve an acceptable occlusion, but this does result in a degree of facial dysmorphology (see Fig. 4-20). Unless upper airway obstruction with obstructive sleep apnea is confirmed, the degree of maxillomandibular deficiency is such that a surgical consult is generally not requested.

An infant, child, or young adolescent who sustains *injury to the craniofacial skeleton* has the potential for growth disturbance of the injured bones. This is in addition to any skeletal deformity that remains if the fracture was not fully reduced with satisfactory initial healing (see Chapter 35). During some difficult deliveries through the vaginal canal, especially those that require forceps, damage to one or both of the temporomandibular joints or fracture of the mandible can occur. In modern times, with good prenatal care and skilled obstetrics support being available at the time of delivery, birth trauma to the mandible has become a rare event.

A childhood injury to the *cartilage of the nasal septum* may result in nasal deformity. It may also lead to deficient midface growth (see Fig. 35-2).[38] This has been confirmed in experimental animals and documented through clinical observation in humans.[28] In experimental animals, when the cartilage of the nasal septum is removed before growth is complete, there will be a dramatic decrease in the horizontal and vertical growth of the midface. Whether this is the result of a mechanical collapse with a secondary loss of growth velocity of the maxilla or an intrinsic growth restriction of the upper jaw remains open to question.

Trauma to the growing mandible that is severe enough to cause fracture and the displacement of the fragments is also known to result in secondary progressive growth deformities, at least in some cases. There are thought to be three major sites of mandibular growth that may be affected:

1. The mandibular condyle: Proliferating cartilage at the base of the fibrocartilage layer that covers the articular surface results in mandibular growth. At the completion of mandibular growth, the fibrocartilage layer is replaced by bone.
2. The outer surfaces of the ramus: Extensive remodeling of the mandible through the apposition of bone on the posterior and outer surfaces along with resorption on the anterior and inner surfaces is known to occur and is influenced by muscle forces and the compression of the associated soft tissues (e.g., tongue volume) within the mouth.
3. The alveolar process: New alveolar bone is added only as individual teeth develop and erupt into the arch.

In individuals who sustain a *displaced condylar neck fracture,* a sequence of events generally occurs that includes the contraction of the lateral pterygoid muscle with the displacement of the condylar fragment anteriorly and medially (Fig. 4-39). The displaced fragment (i.e., the medial pole of the condyle or the total condyle) has a tendency toward a degree of resorption and malunion. This may then result in a loss of posterior facial height, with a shift of the ipsilateral

• **Figure 4-38** A 17-year-old boy who was born with a nonprogressive congenital myopathy was referred by an orthodontist for surgical evaluation. The lack of masticatory muscle strength resulted in a constant open-mouth posture. The long face growth pattern is characterized by vertical maxillary excess, a clockwise rotated retrusive mandible, a vertically long and retrusive chin, and an anterior open-bite malocclusion. The patient underwent a combined orthodontic and surgical approach. Four bicuspid extractions relieved dental crowding. This was followed by surgery that included a maxillary Le Fort I osteotomy (vertical intrusion and horizontal advancement); bilateral sagittal split osteotomies of the mandible (horizontal advancement); and osseous genioplasty (vertical reduction and horizontal advancement). **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction. **C,** Profile views before and after reconstruction.

mandible toward the affected side. In these cases, an asymmetric retrusive lower jaw and predictable malocclusion can be documented when the jaw is placed in centric relation. Experimental and clinical studies confirm that the ability of the individual's mandible and masticatory muscles to adapt will determine the degree of eventual jaw deformity and residual malocclusion as well as what treatment is needed (see Chapter 35).

When significant *condylar trauma* occurs during childhood, with or without fracture, there will have been injury to the fibrocartilage, with a potential effect on growth. If in fact the "condylar cartilage–push theory" of mandibular growth is all important, a devastating growth distortion should occur over time in all affected individuals. Walker tested this theory by deliberately producing condylar fractures in young monkeys and then observing the effect of these fracture on subsequent growth.[131,132] He was unable to document a consistent progressive mandibular deficiency or deformity with malocclusion. Mandibular growth that approximated normal occurred in the majority of experimental animals. Late postmortem gross and histologic evaluation confirmed that there was regeneration of the condylar process with a new layer of cartilage over the articular surface that was identical to the contralateral (noninjured) side. Clinical studies on a series of human children who sustained similar condylar neck fractures confirmed the potential to regenerate bone that approximated the lost (injured) condyle adverse effects on growth in many of the cases.[42,74] It also became evident from these studies that a notable minority (approximately 25%) of affected individuals do sustain significant growth disturbances (i.e., mandibular hypoplasia or asymmetry) after a condylar injury, often with secondary deformity in the growing maxilla (see Fig. 4-39). The explanation for this variation in human response (i.e., repair versus deformity) is likely dependent on the following: 1) the extent of initial injury; 2) the extent of resulting scarring or the lack of regenerative potential; 3) the variable importance of the condyle as a growth center in each individual child; and 4) the variable adaptive ability of the muscles of mastication (see Chapter 35).

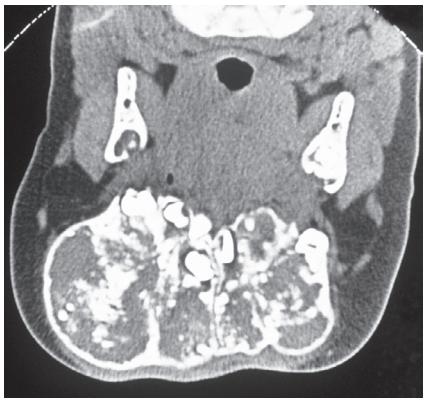
Over the decades, clinicians have confirmed the work of Gilhuus-Moe [42] and Lund[74] by documenting a spectrum of possible outcomes after condylar fracture. Reports confirm instances in which the fracture dislocation of a condylar process has occurred and is followed by a continued normal downward and forward translation of the mandibular body with regeneration of a neocondyle back to baseline. Other clinical reports show a complete loss of the condylar morphology without regeneration followed by decreased posterior facial height, ipsilateral mandibular hypoplasia, and secondary deformity of the contralateral side of the mandible, the maxilla, and the chin region. This sequence of events results in significant maxillomandibular asymmetry and disproportion (see Fig. 35-8). There are also numerous reported examples of bony ankylosis of the condylar stump to the glenoid fossa after the fracture of the condyle (see Fig. 35-1).

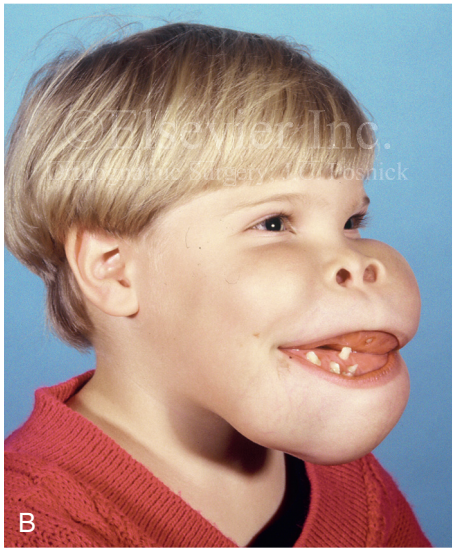
Effects of Tumors and Growths on Skeletal Growth

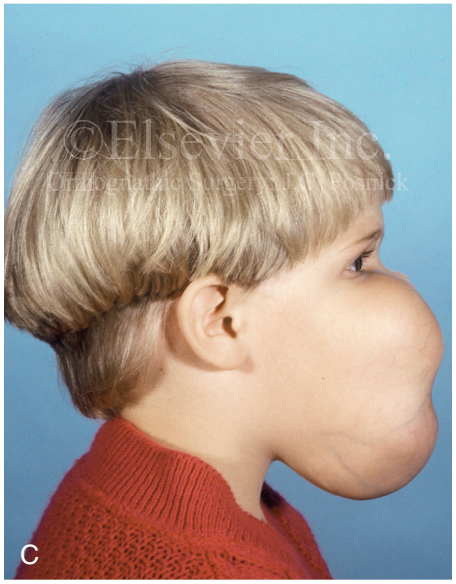
The presence of a sustained *expansile mass* (e.g., cyst, cellular tumor, skeletal mass) will distort the normal growth and morphology of the bones that are being compressed or expanded.[1,6,9,20,24,26,34,46,87-89,95-99] Frequent examples of this occurrence in the maxillofacial region include the effects of neurofibromatosis, vascular malformations, Proteus syndrome, fibrous dysplasia, and odontogenic tumors and cysts (Fig. 4-40). In the adult, the *compressive forces* of a tumor mass may cause resorption and even result in pathologic fracture. The tumor mass may also compress visceral structures and cavities, thereby causing an impairment of function. Depending on the tumor's location, volume, and velocity of expansion, there may be alterations in cognitive function, vision, speech, breathing, swallowing, chewing, lip control, hearing, neck range of motion, or mandibular range of motion. When radiation therapy is required for the management of a malignancy, damage to the adjacent soft tissues and skeletal structures frequently occurs. The arrest of growth in irradiated immature bones may result in orbital dysplasia, zygomatic hypoplasia jaw deformity with malocclusion, and damage to the developing teeth and periodontium (Fig. 4-41).

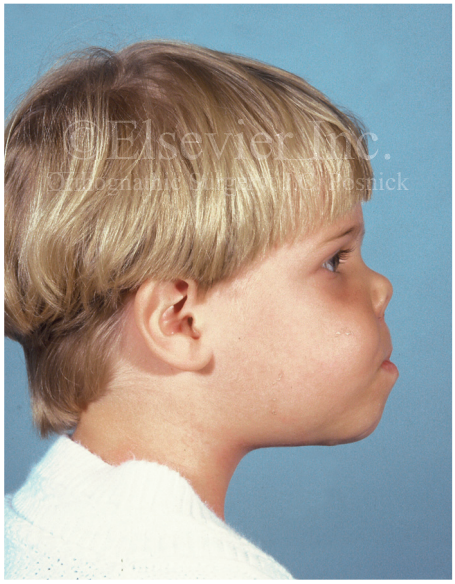
Conclusions

The term *dentofacial deformity* is generally used to describe a significant disproportion of the jaws that is associated with malocclusion. Knowing the etiologic factors of a jaw deformity can be important to the fundamental understanding of how and when to treat the problem. According to current knowledge, factors that are known to cause or result in dentofacial deformities can be subdivided to include known syndromes and anomalies, hereditary tendencies, environmental and neuromotor effects, effects of trauma, and effects of tumors and growths.









• **Figure 4-40** A 5-year-old girl with polyostotic fibrous dysplasia with massive involvement of the maxilla and mandible bilaterally. An asymmetric swelling of the mandible (left greater than right) was first recognized when the child was 18 months old; it rapidly enlarged, and maxillary involvement became evident with the deterioration of breathing, chewing, speech, and swallowing. Pathologic fractures were sustained in all four extremities as a result of the involvement of fibrous dysplasia. **A,** Frontal and computed tomography scan views before surgery. **B,** Oblique facial views before and after reconstruction. **C,** Profile facial views before and after reconstruction.

• **Figure 4-41** A teenage girl who at 9 years of age was found to have a malignancy of the parameningeal region. Biopsy confirmed the diagnosis of rhabdomyosarcoma. She was treated with surgical debulking, chemotherapy, and radiation according to intergroup protocols. There was resulting radiation growth disturbance of the skeletal and soft-tissue structures. The patient underwent staged reconstruction, including stage I serratus muscle microvascular transfer to the left temporal region in combination with full-thickness autogenous cranial graft reconstruction of the left zygomatic orbital complex when she was 13 years old. This was followed when she was 16 years old by further staged orthognathic reconstruction to manage the jaw deformity and the malocclusion. The orthodontic portion of her treatment was carried out cautiously, because there was radiation injury to her left posterior maxillary and mandibular dentition. The procedures included maxillary Le Fort I osteotomy in two segments with interpositional autogenous iliac (hip) grafting, bilateral sagittal split ramus osteotomies of the mandible, and an osseous genioplasty. Septoplasty, inferior turbinate reduction, and recontouring of the floor of the nose were also carried out to open the airway. **A,** Facial and occlusal views are shown when the patient was 12 years old, before reconstruction. **B,** Oblique facial and computed tomography scan views when the patient was 12 years old, before reconstruction.

Orthodontic Treatment Philosophy

In current clinical practice, orthodontic therapy is carried out to provide an idealized occlusion, to enhance facial aesthetics, and to contribute to the individual's overall health and self-image. Through manipulation of the periodontal apparatus, orthodontic treatment has the potential to not only improve occlusion and periodontal relationships but to facilitate their maintenance over a lifetime. For those individuals with dentofacial deformities, orthodontic treatment is indispensable to remove dental compensations, thereby allowing for the correction of the jaw relationships while providing optimal occlusion and periodontal health. Orthodontics has come a long way since 1972, when Dr. T.M. Graber stated the following in the standard textbook of the day:

> *"Orthodontic therapy can produce dire consequences that will later require the services of the periodontist or even the prosthodontist. The limitations of orthodontic treatment are stringent. The [useful] role of tooth sacrifice [and/or orthognathic surgery] must be recognized. Traditionally, orthodontists had their patients wear retaining appliances indefinitely after the removal of tooth moving appliances and attributed any change back toward the original malocclusion to 'the wisdom teeth' or 'the lack of patient cooperation wearing the removable retainer as instructed.'"*

Current issues in orthodontic therapy are, for the most part, no longer just a matter of what attachments or mechanical approaches to use.* Contemporary orthodontics focuses on accurate diagnosis and a basic philosophy of treatment to enhance facial aesthetics and to correct dysfunction. The role of orthognathic surgical interventions and coordinated comprehensive dental rehabilitation to achieve the most favorable outcome should always be considered.[110]

Malocclusions result from a combination of environmental influences and the patient's morphogenetic hereditary predisposition (see Chapter 4).[1,11,15,18,43,44] The dental alignment that naturally occurs in each individual is greatly influenced by the baseline jaw relationships as well as by his or her daily postural masticatory and airway function.† In the presence of a dentofacial deformity, the mere orthodontic movement of the teeth into a "better" interdigitation will not establish normal jaw relationships nor will it correct the head and neck dysfunctions that contribute to or result from the malocclusion.[147,157,179-181] The observed crowding of the teeth generally reflects nature's attempt to establish a homeostatic balance among the available space in the alveolus, the size of the teeth and the dental roots, the position and size of the jaws, and the constant molding and balancing effects of the masticatory and facial musculature with regard to daily function.[6,146,147,162-165,182,183]

The Biologic Basis for Orthodontic Tooth Movement

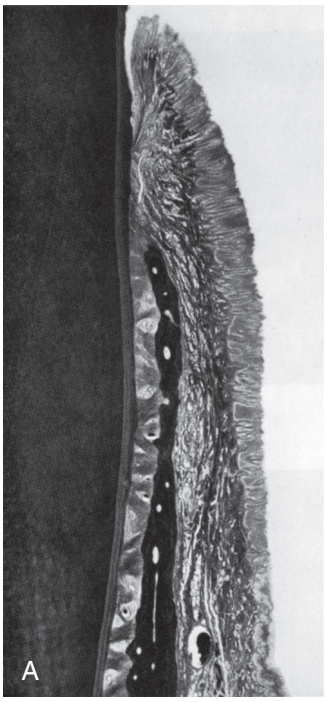
Currently, there are a plethora of appliances than can accomplish almost any desired change in the alignment of the teeth.[69,72] From a purely mechanical perspective, orthodontists are trained in the techniques of tooth movement with the goals of improving dental alignment in each jaw and achieving "ideal" occlusion between the upper and lower arches. The orthodontic movement of the teeth is based on the principle that, if prolonged pressure is applied to a tooth, movement will occur as the bone around the tooth remodels. This is primarily a periodontal ligament phenomenon. In the process, bone is selectively resorbed in some areas and deposited in others. The bone that surrounds the tooth responds to the applied force through intermediate structures (periodontal ligaments), and the objective is for the tooth to move without the loss of crestal height or cortical plates while carrying its attachment apparatus along with it. The whole socket must migrate along with the tooth during this process.

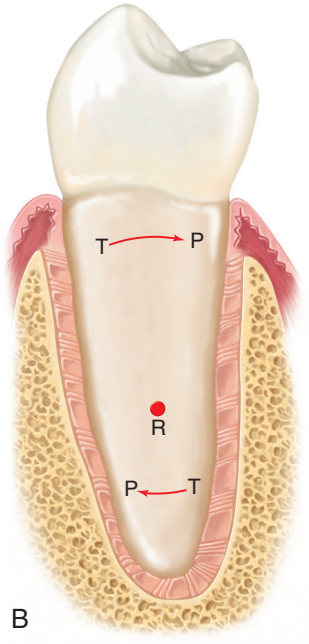
When orthodontic therapy is used to move teeth outside of a biologic envelope, extended treatment time, the potential for periodontal sequelae, and a less-than-ideal long-term occlusion are the likely consequences.[70,86,178] These may occur as a result of the following: (1) attempts to further compensate the position of the teeth toward the skeletal disharmony and outside of the alveolar housing; (2) dental (root) crowding within limited available alveolar bone; or (3) ongoing nasal airway obstruction with an open mouth posture and inadequate lip coverage of the incisors.[4,8,9,32,73,85,193]

Periodontal Ligament Structure and Function

Unless ankylosis is present, each tooth is connected to and separated from the adjacent alveolar bone by a specialized collagen supporting structure known as the *periodontal ligament* (PDL) (Fig. 5-1). The PDL normally occupies a space of approximately 0.5 mm around all parts of the tooth root. The PDL is comprised of a network of parallel collagenous fibers that insert into the cementum (i.e., the covering of the root surface of each tooth) and then into a dense bony plate (radiographically, this is called the *lamina dura*) that is adjacent to each tooth within the alveolar bone. These supporting PDL fibers are angulated between the root of the tooth and adjacent bone; they attach apically on the root and extend occlusally to the adjacent bone. Biomechanically, these angulated PDL fibers act as shock absorbers by helping to resist forces that are applied to the tooth during normal chewing function.

Within the periodontal ligament space, there are cellular elements (i.e., mesenchymal cells, nerve endings, and vessels) and interstitial fluid. The primary *cellular elements* (i.e., mesenchymal cells) are thought to differentiate to form the fibrocytes and the osteocytes. The *collagenous elements* of the PDL are constantly being renewed and altered, depending on the level of functional stress that they are undergoing. The remodeling and recontouring of the alveolar bone is a necessary component of orthodontic tooth movement, and it is dependent on specialized cells (Fig.





• **Figure 5-1** **A,** Principal fiber bundles of the periodontal ligament on the facial surface of a mandibular premolar (silver stain). **B,** Distribution of faciolingual forces *(arrows)* around the axis of rotation *(R)* in a mandibular premolar. The periodontal ligament fibers are compressed in areas of pressure *(P)* and taut in areas of tension *(T)*. *Part A from Glickman I:* Clinical periodontology, *ed 4, Philadelphia, 1972, W.B. Saunders Company, Figures 2-3 and 2-8, pp 34 and 38, respectively.*

5-2). As part of the remodeling process, bone is removed by osteoclasts that are thought to be derived from the *mesenchymal cells*. Cementum is removed by specialized cementoclasts, which are also derived from mesenchymal cells. Nerve endings attach to the PDL and to the blood vessels that surround them. The nerve endings are effective for proprioception and for the perception of pain. The *interstitial fluid* found within the PDL space is derived from the vascular network. It serves as a nutrient source, and it contributes to the shock-absorbing mechanism to better withstand the physiologic forces as well as any pathologic forces that are applied directly to the teeth.

Response of the Teeth and the Periodontium to Normal Occlusal Function

During normal chewing function, the teeth are subjected to intermittent forces that are then transmitted to the periodontal structures.[55,88,89,92,118,192,209] When forces are applied to a tooth, the load is dissipated by the periodontal ligament and the interstitial fluid within the tooth socket. These mechanisms allow a more limited force to then be transmitted to the cortical bone that surrounds the tooth socket (i.e., the lamina dura), which "bends" in response. The term *bending* is used to describe the physiologic response to normal masticatory forces. The bone bending that occurs in response to normal (chewing) function is thought to be an important stimulus to osseous regeneration and repair. This intermittent but repetitive stress loading allows for the modification of the bony architecture as an adaptation to functional demands. If pressure against the tooth is maintained (as opposed to being intermittent, as when chewing), the interstitial fluid within the tooth socket is expressed (i.e., pushed out) and the tooth itself is displaced, thereby compressing the PDL directly against the adjacent bone. This is perceived by the individual as being quite painful, and, if the force is excessive and prolonged, a different physiologic response occurs. This "trauma from occlusion" is a response in which the remodeling of the adjacent compressed bone occurs. A definition of the term *traumatic occlusion* was first provided by Stillman in 1917. He stated that traumatic occlusion is "a condition where injury results to the supporting structures of the teeth by the act of bringing the jaws into closed contacts."[171] The definition given by the American Association of Periodontics in 1986 is "an injury to the attachment apparatus as a result of excessive occlusal force."[171] *Primary occlusal trauma* involves excessive forces on a normal periodontium, and *secondary occlusal trauma* is considered to have occurred when normal forces are placed on a compromised periodontium (see Chapter 6).

The intentional application of these principles is how controlled orthodontic tooth movement occurs. The application of light prolonged vector-controlled forces allows for more or less predictable man-made movements of the teeth. Interestingly, nature's application of these light prolonged forces on the teeth can also occur from maintained posturing of the muscles of the lips, cheeks, and tongue as they press against the teeth, thereby causing dental movement and remodeling of the alveolar ridge. When postural forces from the lip, cheek, or tongue are pathologic, they may contribute to the classic dental compensations that are seen with each specific pattern of developmental dentofacial deformity.* These environmental forces may then be compounded by iatrogenic orthodontic dental compensation maneuvers to further affect periodontal health. For example, consider the retroclination of the lower anterior teeth that is seen with Class III skeletal patterns (Fig. 5-3) (see Chapter 20) or the proclination of the lower incisors that is seen with skeletal Class II cases (Fig. 5-4) (see Chapter 19). In both instances, negative periodontal sequelae may occur.

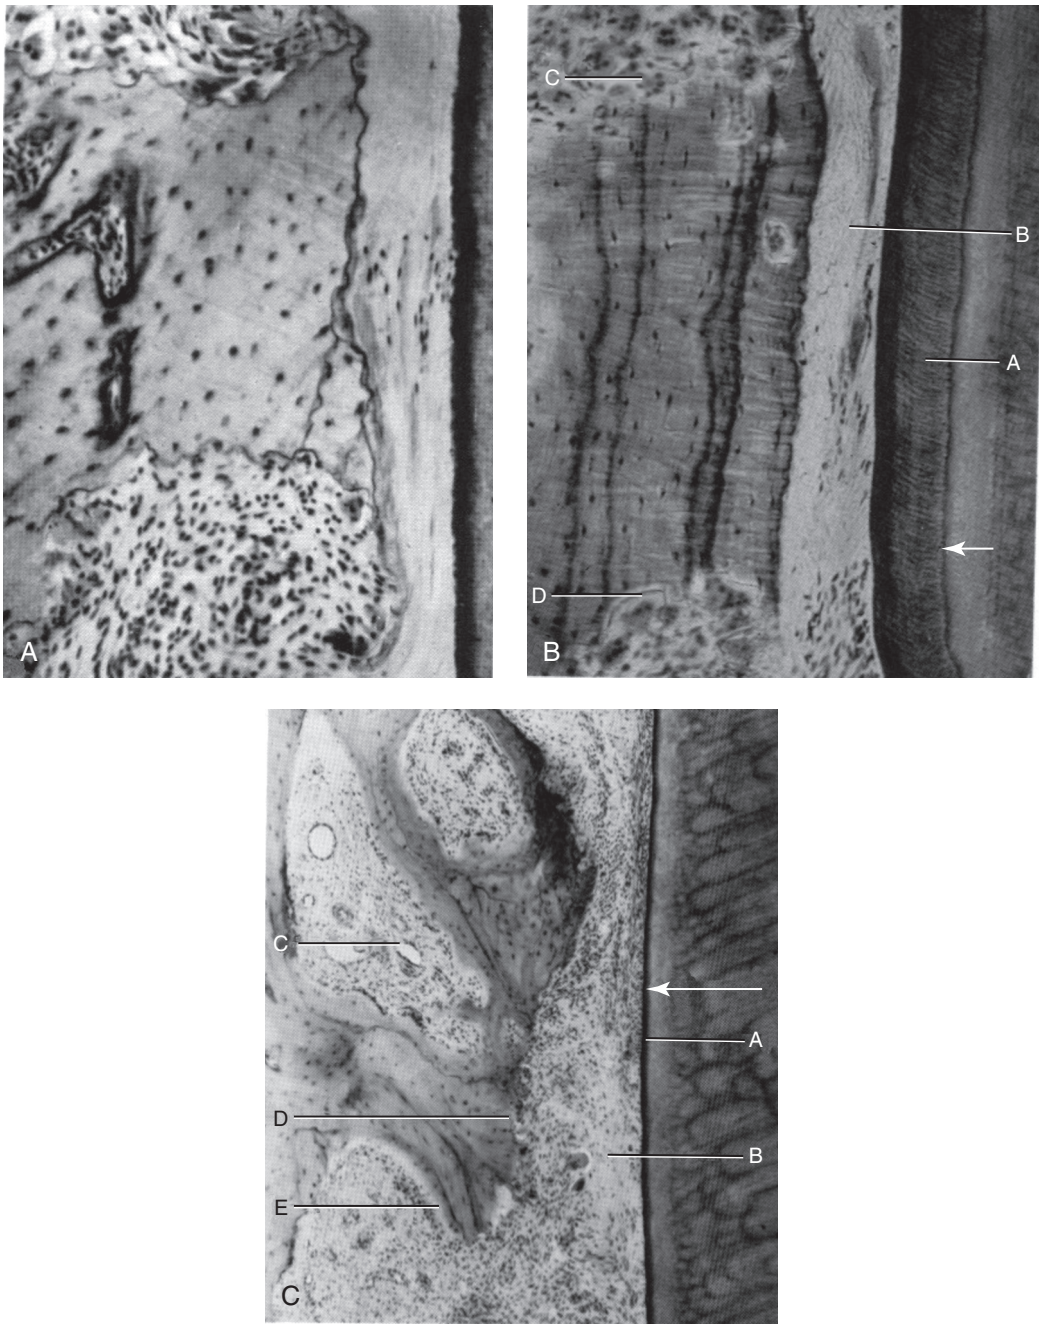
Orthodontic Tooth Movement

The Periodontal Ligament and Bone Response to Sustained Orthodontic Force

The specific anatomic response to orthodontic forces is dependent on the force magnitude. *"Heavy" forces* often result in pain, necrosis of cellular elements within the PDL (i.e., hyalinization), and remodeling with the resorption of the alveolar bone that is being compressed (i.e., the hyalinization zone). It may also result in the resorption of the root apex, remodeling with the loss of crestal bone, and fenestrations or dehiscence through the cortical plates. When *light and constant forces* are applied to the tooth, there is compression without necrosis of the PDL elements and remodeling of the tooth socket without significant irreversible necrosis. As long as the tooth is being moved into adequate alveolar bone and the forces are light, the root of the tooth is less likely to resorb, and the alveolar crest height and cortical plates are for the most part preserved.[30] The objective of the orthodontic movement of a tooth is to produce the desired new tooth position as quickly as can be done, with as little damage as possible to the tooth, the PDL, the alveolar bone, and the adjacent teeth.

There are two major theories to explain the observed process of orthodontic human tooth movement: the *bioelectric theory* and the *pressure-tension theory.* The bioelectric theory holds that the changes in bone metabolism that are required to effectively move teeth and their sockets are controlled by the electric signals produced when alveolar bone bends and the crystalline structure is distorted. The pressure-tension theory presumes that cellular changes occur when pressure or tension is applied within the PDL or tooth socket, which then produces chemical changes. The pressure and tension that occur within the PDL result in specific blood flow changes and the release of chemicals that

*References 50, 58, 75, 76, 91, 93-97, 119, 127, 134-136, 141, 150-152, 167, 213, 216, 229



• **Figure 5-2** **A,** Undermining resorption in a 12-year-old child. This is a view from a short-rooted premolar tooth. The cementum that covers the root surface has not been broken, although the periodontal membrane is hyalinized at the area of greatest pressure. A spicule of bone is being attacked from above and below, away from the compressed PDM. **B,** Undermining resorption is taking place in a 39-year-old adult. No osteoclastic activity occurs in the compressed PDM, but osteoclasts are at work on bundle bone that has been laid down previously from above and below the area of greatest pressure. *A,* Thick cementum layer. *B,* Hyalinized periodontal ligament. *C* and *D,* Frontal undermining bone resorption on both sides of the cell-free area. **C,** Tooth movement with light forces. • **Figure 5-3** A 34-year-old man arrived for the evaluation of a long-standing jaw deformity with malocclusion, chronic obstructive nasal breathing, and periodontal issues. Since his early childhood years, he was known to have a maxillary deficiency with a relative mandibular excess growth pattern. The family elected a camouflage orthodontic approach that included four bicuspid extractions and the introduction of dental compensation in an attempt to neutralize the occlusion when he was 10 to 15 years old. He was a forced mouth breather as a result of the associated increased nasal airway resistance. He underwent septoplasty when he was 20 years old, but this did not result in significant improvement. His general dentist confirmed labial bone loss and gingival recession of the mandibular anterior and maxillary posterior dentition. He was referred to this surgeon, and a comprehensive orthognathic and dental rehabilitation approach was recommended. Consultations with a periodontist, an orthodontist, and an ear, nose, and throat specialist were carried out. The patient was confirmed to have residual deviation of the septum and enlarged inferior turbinates, which explained the continued difficulty that he had with breathing through his nose. A degree of root resorption of the anterior dentition was confirmed. The need for gingival grafting to attain improved root coverage and to generate a wider band of attachment was recommended (i.e., teeth nos. 3, 11, 14, 19, 20, 23 through 26, 29, and 30). This will be followed by the orthodontic removal of dental compensation and then orthognathic and intranasal procedures to improve long-term dental health, to enhance facial aesthetics, and to open the upper airway. **A,** Frontal facial and occlusal views before retreatment. **B,** Profile facial view and lateral cephalometric radiograph before retreatment. **C,** Panorex radiograph with retreatment in progress.

• **Figure 5-4** A man in his early twenties with a primary mandibular deficiency growth pattern. During his teenage years, he underwent failed growth modification attempts followed by orthodontic camouflage maneuvers that included four bicuspid extractions in an attempt to neutralize the occlusion. Deterioration of the periodontium with labial bone loss and gingiva recession along the mandibular anterior dentition is evident. The patient was referred to this surgeon, and a comprehensive orthognathic and dental rehabilitation approach was approved. **A,** Frontal facial and occlusal views before retreatment. **B,** Profile facial view and lateral cephalometric radiograph before retreatment.

affect cellular function, thereby causing the observed changes in bone architecture. These two theories of bone metabolism are also discussed and debated within the orthopedic literature, and they are not mutually exclusive. Many scientists and clinicians believe that both biologic mechanisms play a role in the remodeling and repair of bone. The pressure-tension theory represents the classic theory of tooth movement. It proposes that chemical rather than electric signals are the stimuli for the cellular differentiation required to alter the tooth socket and ultimately to move the teeth. In either case, when an alteration in blood flow within the PDL occurs and is sustained through pressure that is applied directly to a tooth, the tooth shifts position within the PDL space, thereby compressing the ligament on one side and stretching it on the other. Blood flow is decreased where the PDL is compressed, although it may be increased or maintained in areas in which the PDL is under light tension. Interestingly, if the PDL is overstretched (i.e., if "heavy" tooth forces are applied), then the blood flow may also be decreased on the tension side. It is easy to understand how these alterations in blood flow can create changes in the chemical environment. Oxygen levels fall in the areas of compression, although they may even increase on the tension side of the tooth socket. The changes in oxygen content cause a series of biologic responses that bring new cells into the area either through migration or differentiation.

The Amount of Orthodontic Force Applied to the Teeth

The *heavier the sustained pressure,* the greater the reduction in blood flow where compression is occurring in the PDL.[25,166,174] When only *light prolonged force* is applied to a tooth, the partially compressed PDL experiences diminished blood flow, and the interstitial fluids are expressed (pushed out) from the PDL space as the tooth moves within the socket.[125] Animal experiments confirm that, within a few hours, there will be increased levels of cyclic adenosine monophosphate (cAMP).[175] cAMP is known for its importance in the alteration of cell functions. Within 4 hours of continued sustained low pressure, mesenchymal cell differentiation occurs. From a clinical perspective, it is known that, if orthodontic appliances are used for less than 4 to 6 hours per day, not enough sustained force will be applied, and little or no tooth movement will occur.[143,148]

For the tooth to actually move further than just within the socket itself, osteoclasts must arrive (i.e., migrate or differentiate from mesenchymal cells) and then remove bone from the area adjacent to the compressed part of the PDL. Osteoblasts are required to form new bone on the tension side. Prostaglandin E (a family of prostaglandins that are often used pharmaceutically in medicine) has been shown to increase its levels during this phase of orthodontic tooth movement. It is known that prostaglandin E stimulates both osteoclastic and osteoblastic activity, thereby leading to the belief that it is an important mediator of tooth movement.

It is known that the osteoclasts attack the compressed area of lamina dura to remove bone.[184] The radiographic appearance of a widened PDL (on the tension side) in the presence of light prolonged orthodontic forces indicates that tooth movement is soon to begin.[66] On the compression side, osteoclasts are removing the lamina dura. On the tension side, remodeling activity involves osteoblasts laying down new bone. The course of events is different if the prolonged force applied to the tooth is too great. If the force transmitted to the periodontal ligament totally occludes the blood vessels, thereby cutting off all blood supply to the area, generalized necrosis occurs within the compressed area. Although some avascular areas in the PDL will occur even with light forces, if the predominant forces are "heavy," then the response is necrosis. Irreversible damage can then occur, and this includes remodeling with the loss of crestal bone, root resorption, and cortical plate dehiscence. The histologic findings within the PDL—even with light forces during the compression process—show the disappearance of cells within the vessels. The histologic appearance is descriptively said to be "hyalinized" because of its visual resemblance to hyaline connective tissue. After this hyalinization process begins, after several days of delay, the remodeling of bone that borders the sporadic necrotic areas of the PDL will occur as osteoclasts (derived from adjacent undamaged areas) arrive and do their work. The process of bone removal is called *undermining resorption.* This term is visually descriptive when it is viewed under the microscope, because the attack by the osteoclasts is from the underside of the lamina dura. After the *hyalinization* (i.e., the compression of blood flow with isolated necrosis) and the undermining resorption (i.e., the osteoclastic activity on the underside of the lamina dura) have "softened" the lamina dura, tooth movement is soon to occur. The chronology of tooth movement with *frontal resorption* is different than that of undermining resorption. With frontal resorption, a steady attack on the outer surface of the lamina dura results in smooth, continuous tooth movement. With undermining resorption, there will be a delay in the removal of the bone adjacent to the tooth. When heavy force (i.e., pressure) is again reinitiated, there will be a similar delay in tooth movement until a second round of undermining resorption can occur.[171]

The orthodontic movement of a tooth is clinically more efficient when there are only minimal areas of PDL necrosis. As a result, only limited levels of pain are experienced by the individual undergoing treatment. Unfortunately, neither aspect is completely avoidable. To date, a completely smooth progression of tooth movement with consistent light force over time has proven to be unattainable within the human biologic system. One important compounding factor is that the individual who is undergoing orthodontic tooth movement must also continue with the everyday functions of mastication, speech, swallowing, and breathing within a

24-hour cycle. These functions also place forces on the teeth, which may either conflict with or expedite the applied orthodontic forces. Another factor is the relative ineffectiveness of the appliances (i.e., the materials) used to apply sustained appropriate levels of force. To review, in clinical orthodontic practice, on one end of the spectrum, too much sustained force is detrimental to the tissues; alternatively, too little force will not produce the tooth movement that is desired.[25]

Control of Orthodontic Tooth Movement

The basic principle of the ideal orthodontic movement of a tooth includes the application of just enough force to stimulate required cellular activity without the complete occlusion of the blood vessels within the PDL. For example, it is estimated that as little as 30 g of force may be required to tip a single rooted tooth. For controlled resorption and remodeling to occur, force is first delivered to the tooth and then to the PDL, which results in compression, tension, or both at the appropriate locations of the lamina dura. Depending on the desired three-dimensional repositioning of the tooth, different amounts of pressure (i.e., the force per unit area) are applied to different locations along the lamina dura.

The different basic forms of tooth movement include tipping, rotation, and translation. *Tipping* results from a single force applied at a distance to the center of resistance. Although the center of resistance of a tooth is generally located about halfway down the root, the center of rotation for tipping movements is apical to that. Here, the crown will move in one direction, and the apex will move in the opposite direction. When the tooth tips in this fashion, the PDL is compressed most strongly near the root apex on the same side as the force being applied as well as at the crest of the alveolar ridge on the opposite side. Progressively less pressure is created as the center of rotation is approached, where there is minimum pressure applied. During *translation* movement of the tooth, the PDL space is loaded uniformly from the alveolar crest to the apex on the side of tooth compression. A pure translational force will allow for the bodily movement of the tooth rather than tipping. The forces that are required for the bodily movement (i.e., translation) of incisors up to multi-rooted teeth is in the range of 70 to 120 g. This represents the maximum orthodontic tooth movement force to be used in clinical practice. The optimal force for the orthodontic *rotation* of a tooth around its long axis (i.e., 35 to 60 g) is less than that required for the bodily movement of a tooth. The optimal force required for the orthodontic *extrusion* of a tooth is in the range of 35 to 60 g. The *intrusion* of teeth requires the carefully controlled application of consistent very light forces that are applied to the tooth in a specific way. It is difficult to apply controlled intrusion forces to a tooth (i.e., 10 to 20 g) without also applying tipping forces. Small implants (i.e., temporary anchorage devices [TADs]) can be used to help this aspect of tooth movement and to provide greater control, as described later in this chapter.

Control of Force Duration and Decay in the Orthodontic Movement of Teeth

A basic principle in the process of orthodontic tooth movement is the application of *sustained force*. The force must be present for a significant percentage of the time during the whole process of tooth movement. Animal experiments suggest that, only after force is maintained for approximately 4 to 6 hours, will levels of cAMP be measurably increased in the PDL. Appropriate levels of cAMP are thought to be necessary for the stimulation of cellular differentiation. Human clinical experience suggests that a force duration of at least 4 to 8 hours (per 24-hour cycle) is required to effect tooth movement. The teeth can be moved more rapidly if force is maintained for longer durations. In fact, the application of continuous light force (24 hours per day) would produce the most efficient tooth movement. Through technical advances in materials and appliances, the ability to apply continuous force and to control the duration of that force to each tooth has greatly improved. For example, the nickel-titanium alloys and the self-ligating brackets that are in use today have advanced the process of the sustained duration of light force to achieve tooth movement over time. Office visits can often be spaced every 6 to 10 weeks. Applied orthodontic forces are classified as either continuous or interrupted (intermittent). In general, the orthodontist would like to apply *continuous force* (or at least some appreciable fraction of the original applied force) from one patient visit to the next. Orthodontists also use *intermittent forces* for specific purposes. The so-called activated appliances (e.g., removable plates, headgear, elastics) may be used intermittently.

Medication Effects on the Rate of Orthodontic Tooth Movement

The bisphosphonates act as inhibitors of osteoclast-mediated bone resorption, which by definition have an effect on bone remodeling.[5,102] There is evidence to suggest that tooth movement in patients who are receiving parenteral bisphosphonate therapy may be retarded, with a subsequent risk for osteonecrosis of the jaws.[113]

Bartzela and colleagues conducted a systematic review of the literature regarding the effects of medications and dietary supplements on the rate of experimental orthodontic tooth movement.[23] The results of their literature search indicated the following:

- The therapeutic administration of eicosanoids results in increased tooth movement.
- Nonsteroidal anti-inflammatory drugs decreased tooth movement; however, non-nonsteroidal anti-inflammatory analgesics (e.g., Paracetamol [acetaminophen]) had no effect.
- Corticosteroid hormones, parathyroid hormone, and thyroxin have all been shown to increase tooth movement.

- Estrogens probably reduce tooth movement, although no direct evidence is available.
- Vitamin D_3 stimulates tooth movement, and dietary calcium seems to reduce it.

The Role of Anchorage in the Orthodontic Movement of Teeth

The term *anchorage* as it applies to orthodontics refers to the nature and degree of resistance to displacement provided by an anatomic unit (e.g., molars and premolars, temporary skeletal anchorage devices, hard palate) when it is used for the purpose of effecting tooth movement.[139]

The principle of anchorage in the orthodontic movement of teeth is an application of Sir Isaac Newton's realization that action and reaction are equal and opposite. Restated, this means that, for every force that is directly applied, there is an equal and opposite (reciprocal) force. Depending on how the orthodontic force is applied to a tooth and given the fact that each tooth has a different resistance value to tooth movement (as a result of the nonuniform nature of the teeth and the periodontium), the orthodontist may choose to use certain teeth or groupings of teeth (e.g., ligating molars together as a unit) for "anchorage" when moving other teeth into a more desirable position. Sources other than teeth may also be used for anchorage, including TADs, headgear, a facemask, the hard palate, or the lingual or buccal alveolar supporting bone of the mandible.

Dental anchorage is most typically used to overcome resistance to the orthodontic movement of teeth. To assess the anchorage requirements of the desired tooth movement, the clinician must first evaluate the part of each tooth that is anchored into the alveolar bone. The overall anchorage requirements primarily include the number of roots and the shape, size, and length of each root of the teeth that require movement. This is primarily the sum total of the surface area of the root portions of the teeth that are enveloped by alveolar bone and that are to be moved. A tooth (root) with a large surface area (enveloped by alveolar bone) is more resistant to displacement than one with a smaller surface area. A multi-rooted tooth is more resistant to displacement than a single-rooted tooth. A long-rooted tooth is more difficult to move than a short-rooted tooth. A triangular-shaped root offers greater resistance to movement than a conical-shaped root. Other factors are also important, including the following: (1) the relationship with the contiguous teeth; (2) the ongoing forces of occlusion; (3) the age of the patient and the soft-tissue forces on the teeth (i.e., cheeks, tongue, and lips); and (4) the individual's unique tissue response. Thus, molars are generally good teeth to use for anchorage, because they have deeper and longer roots, they have a greater root surface area, and they are less susceptible to tipping forces. As stated previously, anchorage may also be increased by ligating multiple teeth together, thereby summing their individual resistance. Anchorage forces may also be provided by the hard palate, the buccal cortical plate of the posterior mandible, the head (headgear), the face (a face mask), or implants into bone (TADs).

Reciprocal Tooth Movement

When planning orthodontic therapy, the clinician must consider not just the tooth movement that is desired but any *reciprocal effects* that may occur throughout the dental arches as well. Reciprocal effects must be controlled to achieve the desired repositioning of all of the teeth and to establish preferred occlusion. In a completely reciprocal situation, Newton's theory is easy to understand. When the forces applied to similar teeth and to similar arch segments are equal, there will be an equal force distribution in each PDL with this same degree of movement. A classic clinical case analysis that is frequently used to understand the "reciprocal/nonreciprocal" concept is to consider the type of tooth movement that occurs when an elastomeric chain is placed across a first premolar extraction site in the maxilla. This pits the central incisor, the lateral incisor, and the canine in the anterior segment in opposition to the second premolar and the first molar in the posterior segment. The same total force would be felt by the three anterior teeth and the two posterior teeth as the action of the chain is equal in each segment. However, equal reciprocal movement would require the same total PDL surface area over which the force is distributed. Because the measured PDL area for the two posterior teeth is larger than the three anterior teeth, the movement will not be reciprocal. In this typical, real-life clinical setting, the anterior teeth move back into the bicuspid extraction sites more than the posterior teeth migrate forward. If it is desired that the anterior teeth move entirely into the extraction space, reinforced anchorage will be required. This may be accomplished by incorporating the second molar into the posterior unit. This changes the root surface area ratios, which results in additional retraction of the anterior teeth. Other methods of reinforcing posterior anchorage include the use of extra oral force, such as headgear, TADs, and palatal support through the use of Nance appliances or a transpalatal bar.[148]

Cortical Walls as Limiting Factors to Orthodontic Tooth Movement

Cortical bone is more resistant to resorption; therefore, tooth movement is slowed whenever the root to be moved contacts it. This can be problematic, for example, when there is a dense cortical layer of bone formed within the alveolar process of a previously (long-ago) extracted tooth. It can be more difficult to close an "old" extraction site, because tooth movement is slowed to a minimum when the root encounters cortical bone along the resorbing side of the alveolar ridge.[118,126] Tooth movement is also greatly slowed and root resorption more likely when a tooth (or tooth root) is forced against a cortical plate (e.g., a labial plate, a lingual plate), such as may occur during attempts to correct incisor inclination.

In theory, the optimal force level for the orthodontic movement of a tooth is the lightest force (and the resulting pressure) needed to produce the near-maximum preferred response.[176] Forces that are more than "optimal"—although effective for the production of tooth movement—are both unnecessary and possibly traumatic to the tooth, the periodontium, the alveolar ridge height, and the cortical plates.

Negative Sequelae of Orthodontic Forces

Mobility and Pain

During the usual orthodontic movement of teeth, the PDL fibers are stretched on the tension side, which is seen radiographically as a widened PDL space. At the same time, the PDL fibers are compressed on the pressure side, which results in a narrowed PDL space. If forces are excessive, greater degrees of tooth mobility can be anticipated, and this will also involve a complaint of pain from the patient. A similar sequence of events can occur with heavy clenching or grinding of the teeth or in the presence of a traumatic occlusion, which results in excessive force to individual teeth. Excessive mobility will generally correct itself if the force is removed quickly enough.

Heavy pressure applied to the tooth will also result in immediate pain transmitted through the nerve fibers in the PDL. Several hours after normal orthodontic forces are first applied, teeth typically have at least some sensitivity to pressure, such as with the biting of hard objects. Within 2 to 4 days, the pain should dissipate considerably. With current therapeutic orthodontic mechanics, the forces applied should result in very little immediate discomfort.

Effects on the Pulp

The normal therapeutic level of sustained light orthodontic forces on the crowns of the teeth should have little effect on the pulp. The loss of tooth vitality during orthodontic treatment has occasionally been reported in previously traumatized teeth. This should be a rare consequence of orthodontic therapy when light continuous forces are being applied.

Effects on Root Structure

Recent research indicates that, when therapeutic orthodontic forces are applied, there is a degree of injury to the cementum. In current clinical practice, with the use of continuous light forces, this occurrence is less frequent. The repair of any limited cemental injury generally occurs. Alternatively, heavy orthodontic forces—whether continuous or intermittent—may lead to root resorption, because the cementoclasts remove not only cementum but also dentin of the root (Fig. 5-5). The permanent loss of root structure only occurs when an island of cementum and dentin becomes completely separated from the rest of the root surface. When this happens, resorption without reincorporation occurs.[34,37,84,103,121] The permanent loss of root structure related to orthodontic treatment is generally seen at the root apex.

The resorption of the tooth roots during orthodontic treatment has been documented to occur in three distinct forms: (1) moderate generalized resorption; (2) severe generalized resorption (see Figs. 5-5 and 5-6); and (3) severe localized resorption. The shortening of the root length of the maxillary incisors (i.e., severe localized resorption) is seen more often than this condition appears to occur in the other teeth (Fig. 5-7). Although some studies have shown that measurable root resorption can be identified in 90% of maxillary incisors and in more than half of all other teeth during a typical fixed orthodontic appliance treatment, the shortening is almost imperceptible, and it is clinically insignificant for most. Nevertheless, occasionally the loss of one third or one half or more of the root structure is observed in patients who underwent what was considered to be routine orthodontic treatment. When this does occur, it is either severe generalized resorption or severe localized resorption. Fortunately, severe root resorption of all orthodontically treated teeth is not common. When severe generalized resorption does occur, it is often seen without any orthodontic or other forms of active dental treatment, and it may be of an uncertain etiology. If there is evidence of root resorption before orthodontic treatment, the patient should be considered at high risk for further resorption during orthodontic treatment. Radiographs should be taken during treatment to watch for this occurrence. If resorption becomes apparent, the patient is informed, and the treatment plan altered. In contrast with severe generalized resorption, severe localized resorption is more frequently associated with specific forms of orthodontic treatment. Risk factors are likely to include heavy continuous orthodontic forces being place on the teeth and a prolonged duration of treatment. Localized resorption is more frequently seen in the maxillary incisors, when the root apices are forced against the facial cortical plate during treatment. For example, in the clinician's attempts to compensate for a long face Class II skeletal pattern with an anterior open bite, the maxillary incisor crowns may be detorqued (resulting in a loss of proper buccolingual inclination) and vertically lengthened as the bicuspid extraction sites and the open bite are closed. This may cause the incisor roots to come into heavy contact with the labial cortical plate and thus result in so-called "round tripping." Forces must then be reapplied to the incisors to establish adequate palatal root torque.

Effects on the Alveolar Ridge Height, the Cortical Plates, and the Gingiva

When teeth naturally erupt, they bring alveolar bone with them. It is also known that teeth may overerupt and cause excess alveolar bone height. For example, in the presence of a constant open mouth posture during growth, the hypereruption of the maxillary molars will occur (see Chapter 4). This defines the long face growth pattern (see Chapter 21).[92-97] One argument for functional appliance use is to limit this molar hypereruption. The reverse

• **Figure 5-5** A 14-year-old girl was referred by her orthodontist for surgical evaluation. She presented with a jaw deformity and associated malocclusion characterized by maxillary deficiency in combination with asymmetrical mandibular excess. She is congenitally missing teeth (all of the third molars, the maxillary right second molar, the maxillary left second molar, the mandibular left second bicuspid, and the mandibular right second bicuspid), and she has short dental roots. At the time of arrival, she had already undergone attempts at growth modification, including a face mask followed by rapid palatal expansion. At presentation, there was an asymmetrical Angle Class III negative overjet with a bilateral posterior crossbite malocclusion. Current maxillofacial dysmorphology and dental anomalies have negative consequences on the patient's speech, swallowing, breathing, chewing, and lip closure/posture. At this time, the patient agreed to a comprehensive facial and dental rehabilitation approach with a desire to achieve improvements in breathing, lip closure/posture, occlusion, long-term dental health, and enhanced aesthetics. After periodontal and restorative dental evaluation, limited orthodontics and then jaw and intranasal procedures were carried out. The procedures included a Le Fort I osteotomy, sagittal ramus osteotomies of the mandible, an osseous genioplasty, a septoplasty, and inferior turbinate reduction. With finishing orthodontics, restorative dentistry is planned. **A,** Frontal views in repose before and after surgery. **B,** Frontal views with smile before and after surgery.

• **Figure 5-6** A 20-year-old woman was referred by her orthodontist for surgical evaluation. She presented with a narrow maxilla, a significant curve of Spee, and dental crowding. The mandibular arch also had dental crowding, tipping, and rotations. Both jaws lacked horizontal projection, and there was a severe anterior open bite malocclusion. The patient was a forced mouth breather with increased nasal airway resistance as a result of septal deviation, enlarged inferior turbinates, and a high nasal floor. The right maxillary lateral incisor was congenitally absent, and the left maxillary lateral incisor was hypoplastic and rudimentary. The shortness of the roots throughout the maxillary and mandibular dentition is presumed to be congenital. The patient agreed to a comprehensive facial and dental rehabilitation approach with a desire to achieve improvements in breathing, lip closure/posture, occlusion, long-term dental health, and enhanced aesthetics. She underwent periodontal treatment that included the extraction of tooth no. 10, grafting to the labial aspects of the mandibular incisors, and maxillary gingivectomy. This was followed by limited orthodontic manipulation and then jaw and intranasal surgery. The procedures included a maxillary Le Fort I osteotomy in three segments (horizontal advancement, vertical shortening, clockwise rotation, arch expansion, and the correction of the curve of Spee); bilateral sagittal split osteotomies of the mandible (horizontal advancement and counterclockwise rotation); osseous genioplasty (horizontal advancement and vertical shortening); and septoplasty/inferior turbinate reduction. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

effect on the alveolar process is observed at the edentulous space of a congenitally absent tooth (e.g., a retained primary molar with the congenital absence of a mandibular permanent bicuspid). The associated alveolar bone will be concave with limited vertical height (Fig. 5-8). The alveolar ridge volume deficiency at the edentulous site will also have a ripple effect, thereby preventing the full eruption of the adjacent teeth. Another example in which ridge height and volume is affected is when a maxillary canine erupts into a successfully bone-grafted alveolar cleft. Typically, the canine eruption followed by the orthodontic closure of the cleft dental gap will achieve normal vertical height and an improved arch form (see Chapters 32 and 33; Fig. 5-9).

It is also known that, if a tooth is orthodontically intruded, alveolar height will be lost, thereby leaving the same amount of root embedded in the bone as before (i.e., the reverse effect of hypereruption). In this clinical scenario, the movement of the intruded tooth's gingival margin relative to the surrounding teeth will also be observed. TADs and other orthodontic means are often used in an attempt to achieve this objective. Unfortunately, the relapse tendencies after these orthodontic maneuvers remain a concern.

Teeth can generally be orthodontically moved through the alveolus without significant damage being done to the bone.[71,155] The essential point is to move the tooth through the alveolus rather than outside of it. An exception to this is seen in the presence of active periodontal disease or when the orthodontic forces applied are excessive.[128] In this scenario, remodeling with a loss of crestal height and cortical wall dehiscence are likely negative effects to the alveolar bone. If the periodontal disease is first controlled, a normal bone response to therapeutic orthodontic mechanics should be expected (see Chapter 6).[26]

Before orthodontic treatment is initiated, the individual's biotype (i.e., the biologic predisposition of the periodontium) should be considered.[3,87] This includes an assessment of the adequacy of the gingiva and the alveolus. A thick attachment apparatus and a full-volume alveolus are desired. In an adult (even more so than in a teenager), the movement of teeth outside of the alveolar bone housing or without adequate attached gingiva is poorly tolerated (see Figs. 5-3 and 5-4). In addition, the extrusion of the incisors, the buccal tipping of the maxillary molars, and the labial version of the mandibular incisors should be limited. The adult dentition may also be compromised by wear abrasion facets, the presence of poorly designed and poorly fitted restorations, and the pretreatment loss of the periodontium. In addition to standard orthodontics, ideal treatment may require the following: (1) periodontal evaluation and management; (2) the completion of functional restorations; (3) the surgical correction of any existing jaw discrepancy; and (4) the management of edentulous space. Clarifying the willingness of the patient to maintain a hygiene program before the initiation of treatment is also a benchmark requirement to ensure success.

Mechanical Techniques Used in Orthodontic Force Control

Orthodontic tooth movement is best produced by *light continuous force.* Orthodontic appliances in clinical practice strive to use light continuous forces that are neither too great nor too variable over time.[156] The use of sound mechanical principles; an understanding of the available options with regard to materials, appliance design, and anchorage control; and the prevention of a rapid decrease in the orthodontic forces are more or less achievable.

The potential response of each tooth to the mechanical forces that can be orthodontically applied (e.g., elastic modules, wires, springs) must be considered by the clinician when he or she is designing appliances (e.g., fixed, removable) and then orchestrating anticipated dental changes. The orthodontist delivers mechanical therapy with the placement of brackets and bands on the teeth; the use of wires that connect teeth together; the use of springs, coils, and elastics; and with dental and non-dental anchorage control. However, this is always done with an understanding of the overall clinical objectives and pitfalls of treatment.

At times, it may be tempting to pursue an improved occlusion by moving teeth outside of the alveolar housing rather than coordinating treatment with either needed orthognathic procedures or with selective extractions to create necessary space[40,74,98,124,137,219,235] (see Figs. 5-3 and 5-4). These two biologic treatment pitfalls contribute to many of the everyday frustrations that are experienced in clinical practice.[31,41,47,60-62,67,132,133,149,168,195,212,214] The orthodontist should remain vigilant when assessing the degree of dental compensation introduced while attempting to correct the occlusion.[2,24,42,65,82,169,170,194,196,206]

Fixed Appliances Used in Orthodontic Treatment

Edward Angle is considered the father of modern orthodontics (see Chapter 2). His treatment was based on the development of appliances from which all contemporary orthodontics stem.[15,16,138,228] Current fixed appliances in orthodontics are all variations of Angle's edgewise appliance system.[36,112,233] By the late 1800s, orthodontic fixed appliances depended on a rigid framework that was positioned on the outside circumference of the teeth.[214] The teeth were then tied to the rigid framework to move them out to the desired arch form (i.e., expansion) as dictated by the appliance. Angle's *"E" arch* was an innovation on earlier designs. Bands were placed on the molar teeth, and a heavy *U-shaped arch wire* was attached to the banded molars posteriorly. The arch wire was positioned around the labial side of the individual teeth, which were then ligated to it. The wire was gradually unscrewed at the molar location, which resulted in expansion as the arch perimeter increased. The teeth were forced to expand with the labial wire. Unfortunately, the "E" arch was only capable of tipping the teeth into the new

• **Figure 5-8** This 22-year-old man is congenitally missing the mandibular first and second bicuspids and the right maxillary first bicuspid. He has a maxillary deficiency in combination with relative mandibular excess. He underwent earlier compensating orthodontic treatment, but an Angle Class III, negative overjet, posterior crossbite malocclusion remains. With the congenital absence of the permanent lower bicuspid teeth, there is hypoplasia of the associated alveolar ridge. The congenital absence of the bicuspids causes a ripple effect on the vertical alveolar height of the adjacent teeth. **A,** Frontal facial view and occlusal views before definitive orthognathic correction and dental rehabilitation. **B,** Profile facial and cephalometric views before further treatment. **C,** Panorex radiograph before further treatment.

• **Figure 5-9** A child who was born with van der Woude syndrome, including bilateral cleft lip and palate and lower lip pits, was followed since birth by this surgeon. The child underwent lip and palate repair, including lower lip pit excisions, during childhood. He underwent successful mixed dentition grafting and fistula closure before the eruption of the canines. As a teenager, he demonstrated maxillary hypoplasia with secondary deformities of the mandible. He then underwent a comprehensive orthodontic and orthognathic/intranasal surgical approach that included a standard Le Fort I osteotomy (vertical lengthening, horizontal advancement, and clockwise rotation) with interpositional grafting; bilateral sagittal split ramus osteotomies (clockwise rotation); osseous genioplasty (horizontal advancement); and septoplasty/inferior turbinate reduction/nasal floor recontouring (see Fig 33-3). **A,** Frontal views with smile before and after reconstruction. **B,** Profile views before and after reconstruction.

position. In addition, it could not precisely differentially position individual teeth over the dental arch. Angle then began to band each individual tooth (not just the molars), and he refined the connection of each banded tooth to the labial arch wire. This allowed him to move each tooth toward the wire at different rates to round out the arch. This technique required ingenuity and a sophisticated mechanical understanding of the process. Accomplishing these maneuvers had a steep learning curve, and it was not easily grasped by clinicians in practice. Angle's next appliance innovation modified the tube (band) that was placed around individual teeth to include a vertically positioned rectangular slot. The *ribbon arch* was made of gold wire, and it remained on the labial side of the arch.[63] The gold wire was inserted into the slot (bracket) on each banded tooth and held in place with a pin. This improved the efficiency of the alignment of malpositioned teeth. Unfortunately, these appliances still did not achieve consistent bodily movement of the teeth. Tipping of the teeth continued to be problematic. To overcome the deficiencies of the ribbon arch, Angle reoriented the slot (i.e., the shape and location of the bracket on the labial side of each banded tooth) from vertical to horizontal and then inserted a rectangular labial arch wire. He also coined the term *edgewise.* The edgewise appliance allowed for the improved control of crown and root positioning in all three planes of space. By the early 1930s, Angle's *edgewise appliance* became the mainstay of fixed orthodontic appliance therapy.[222] The *rectangular arch wire* was tied into a *rectangular slot* on the labial side of each tooth with additional wire ligatures; pins were no longer used. This further improved the control of the root position (i.e., it limited tipping) during the movement of the teeth.

Eyelets were added to the corners of the bands on each tooth, which could be tied into the labial arch wire as needed for rotation control. Angle was the first clinician to place attachments on each individual tooth to achieve the precise repositioning of each tooth toward a labial arch wire.

Interestingly, Angle's edgewise appliance system was also able to provide the level of control of root position that was necessary during the process of tooth movement to close an extraction site. If Angle had known that his appliance would be used in this way, he likely would have prevented its development. Charles Tweed, who was initially an Angle disciple, adapted the edgewise appliance for this purpose.[214] He did so after he observed significant relapse in many of his own non-extraction (i.e., arch expansion) cases. After he made a decision in favor of extraction, he was able to move the teeth bodily into the bicuspid extraction site with molar anchorage control. The teeth were then able to be retracted into the extraction sites with *closing loops,* one at a time (canines first, incisors second). In Australia, Begg adopted the *ribbon arch appliance* (rather than the rectangular wire) to close extraction sites.[223] He felt that it provided better control of the root position. He first tipped the anterior teeth with light continuous forces and then used torquing and uprighting auxiliaries to complete tooth alignment. When this was coupled with the detorquing of the incisors, root resorption sometimes occurred.

Orthodontic appliances were further modified to allow for rotational control without the need for additional ligatures.[11-14,54,107,108,111,190,191] This was accomplished by using either *twin brackets* or *extension wings with single brackets* that could contact the underside of the arch wire. Further modifications included the alteration of the bracket slot dimension, *self-ligating brackets,* and the addition of *lingual appliances.* With improvements in dental materials, *bonding attachments* (i.e., brackets) that were applied directly to the tooth surface (rather than the banding of teeth) became popular. Bonded attachments have no interproximal component and therefore require no separation of teeth, and they are less painful for the patient. They are more efficient for the clinician to put on and to remove, and they are more aesthetic because they are less visible to the casual observer at conversational distance. Clear and tooth-colored appliances have also been developed. An additional advantage to direct bonded brackets and tubes is improved access for oral hygiene and periodontal maintenance.

Contemporary edgewise appliances still remain an integral component of orthodontic treatment.[99] Brackets or tubes are customized for each individual tooth, thereby allowing for the minimum number of bends in the arch wire that are necessary to produce an ideal arrangement of the teeth. This *"straight wire"* approach requires some bending of the wire to allow for a passive fit of the arch wire when the teeth are ideally aligned.

Auxiliary attachments are components of the edgewise appliance system and include the following: (1) headgear tubes; (2) auxiliary edgewise tubes; (3) auxiliary labial hooks; and (4) lingual arch attachments. Headgear tubes can accept heavy auxiliary labial arch wires. Auxiliary edgewise tubes allow for the application of segmental arch mechanics. They are generally used for the intrusion of teeth, and they are placed gingival to the plane of the main arch wire. Auxiliary labial hooks can be used for intra-arch elastics, but they require meticulous oral hygiene. Lingual arch attachments can also be used for adjunct anchorage control.

Bracket Materials and Design

Orthodontic brackets are generally made from various classes of stainless steel.[99,112,140] More often than not, they are made by a metal injection molding process rather than milling. Clear brackets that are made of reinforced resin composite or alumina have become popular; this aesthetic option is often requested by the patient. Friction forces created between metal arch wires and ceramic brackets have largely been overcome by designs that incorporate a metal slot in the bracket or by reducing surface roughness within the slot. *Self-ligating brackets* are classified as either passive or active, depending on how the wire is held in the bracket slot. Both types of self-ligating brackets can offer low friction with a reduction in the anchorage requirements and less chair time without a loss in the quality of the results. The term *prescription* is used in orthodontics to describe the angulation, inclination, and offset values used in the bracket system to treat a particular patient's malocclusion. Traditional prescriptions have been based on the systems of either Roth or Andrews, although many variations exist.[12-14,190,191] Current prescriptions often use newer arch wire and bracket technology and involve claims of improved treatment efficiency. For example, *SureSmile* uses a variety of prescription brackets in conjunction with computer-generated, pre-bent prescription wires for faster and more accurate detailing and finishing. The *Insignia system* also uses a computer to mill special brackets for each tooth of each patient. The brackets are then bonded indirectly to each tooth with the use of transfer jigs. The *Incognito system* creates custom-made gold brackets for lingual orthodontics. This method of tooth movement has gained popularity in Europe, and it is also used in the United States. Problems with all of these prescription techniques may arise if they are improperly used by a clinician for an individual with a jaw deformity. If attempts are made to correct the malocclusion by orthodontic mechanics alone, the preset wires will result in excessive dental compensation with injury to the dentition and the surrounding periodontium as the teeth are compressed against the cortical plates and pulled out of the alveolar housing. However, when properly incorporated into a comprehensive orthodontic and orthognathic treatment plan, these newer techniques may improve results and involve reduced treatment times.

The banding of individual teeth has been used in orthodontics for more than 100 years as a method to gain attachment to the teeth. With the introduction of the acid-etch technique, the anterior teeth, as part of orthodontic therapy,

are commonly bonded rather than banded. The bonding of molar teeth has also become more common in clinical practice, which is due at least in part to improvements in light-cured adhesive technology and bracket design (i.e., a contoured bracket design and a micromesh base). In addition, the cost of bonded molar tubes has come down, and the avoidance of molar banding means that the separation of the teeth for the placement of the bands is no longer required.

Cements and Adhesives

The spectrum of cements and adhesives used in orthodontic practice includes self-etching primers, wet bonding, fluoride release to prevent demineralization, light-cured band cements, colored cements, and curing lights.* *Self-etching primers* are now available for orthodontics. They are relatively moisture insensitive, but they may have reduced bond strength as compared with the conventional acid-etch technique. The *wet bonding products* (i.e., modified resin-filled glass ionomer adhesives) that are currently available show lower bond strengths with a higher failure rate than conventional composite, but they are generally acceptable for accomplishing needed objectives. Fixed-appliance orthodontics can lead to problems with oral hygiene, increased plaque accumulation, and altered plaque ecology, which may lead to enamel demineralization. Fluoride in the oral environment has been shown to lead to altered bacterial function, reduced enamel dissolution, and increased remineralization. *Fluoride-releasing bonding cements* have been shown to reduce the depth and extent of demineralization microscopically. Unfortunately, long-term success with regard to the limiting of demineralization has not been significantly demonstrated. *Conventional glass ionomers* are still the preferred material for use beneath molar bands to limit demineralization as compared with cements that do not release fluoride. *Polyacid-modified composite cements* are now available to secure bands, and they offer a light-cured snap set. These new cements appear to clinically perform as well as conventional glass ionomer cement, but, because they do not bond to enamel, they may result in greater demineralization in some patients. High-performance *halogen curing lights* are now available; these contain bulbs that do not degrade over time, and they have curing times of 5 to 8 seconds. *Plasma arc lights* are also available; these can cure adhesive in 3 to 5 seconds, but they have the disadvantage of generating much heat during the process. Currently available *light-emitting diode curing lights* are gaining popularity; they generate low levels of heat, and they are cordless.

Arch Wire (Materials and Design)

Before the 1950s, precious metal alloys were the commonly used materials for orthodontic arch wires. Stainless steel alloys surpassed gold as the preferred arch wire materials during the 1940s to reduce costs, to provide higher-yield strength and stiffness, and to result in higher elastic modulus and flexibility with improved properties to orthodontically close dental space. These alloys generally included platinum and palladium, which were often mixed with gold and copper. During the 1970s, NASA developed a nickel-titanium alloy that was easily deformed at low temperatures but that was able to memorize its original shape with warming (i.e., the thermal dynamic shape memory effect). The term *active* has been coined to describe this phenomenon. Nitinol was then developed as a cheaper, stabilizing "passive" version of this material, and it has been found to be useful as an orthodontic wire, because it still possessed low stiffness and good recovery when it was used as an aligning or intermediate arch wire. Currently, two active nickel-titanium alloy forms of this material are used in orthodontic practice, because they both possess excellent elastic properties. This includes the *strength-induced superelastic wires* and the *thermally induced superelastic wires*. The term *superelastic* refers to a material that can undergo martensite-austenite phase transformations, which are generated by either mechanical stress or heat. The crystal structure of the wire changes with mechanical deformation, which results in a unique non-linear stress–strain curve in which stress is independent of applied strain. In theory, the force levels that are used to deform the wire to ligate it into the bracket are less than those created by the wire as it attempts to return to its original shape. This offers the advantage of low continuous forces applied to the teeth through the entire reforming process, despite the wire being tied into teeth that are severely displaced. The thermally induced superelastic wire undergoes phase change as the temperature changes from the ambient temperature to an individual's body temperature. The temperature at which the transformation takes place can be specifically controlled during the manufacturing process to match the intraoral temperature requirements. When using thermally induced superelastic wires, the wire is ligated in place during its low-stiffness phase; then, with the heat of the oral cavity, transformation is induced, thereby returning it to its predetermined austenitic form. The theoretical advantage of both of these superelastic wire types is that they are able to provide a physiologic low and continuous force that can be used for leveling and aligning the teeth. Although individual practitioners are advocates of these wires as compared with the more traditional nickel titanium or multi-strand stainless steel wires, significant differences in the speed of alignment between the wire types has yet to be proven.[42]

Intra-Oral Auxiliaries to Brackets and Arch Wires

Intra-oral auxiliaries to the brackets and arch wires include closing and opening coils, torquing and uprighting auxiliaries, elastomeric chains, other non-compliance devices, and temporary skeletal implants. *Elastomeric modules* are commonly used to secure the arch wire into the slot of a non–self-ligating bracket.

*References 10, 38, 51, 56, 105, 120, 144, 145, 153, 154, 172, 173, 177, 202-204, 232, 236

The definition of friction is the resistive force between surfaces that oppose motion. In orthodontic tooth movement, friction results from the interaction of an arch wire with the walls of an orthodontic bracket or a ligature. It is now known that friction is only a small part of the resistance to movement as a bracket slides along in arch wire.[19,39,64,122,208] In orthodontics, tooth and bracket movements have major interactions that involve the teeth, the PDLs, the alveolar bone, and the forces of mastication. For a bracket that is attached to a tooth to move relative to a wire in the bracket slot, the tooth must move. The tooth's resistance to being moved contributes to its resistance to sliding. This is particularly true when bodily movement rather than tipping is desired. Binding and notching will occur in the clinical setting but not in laboratory simulations, where only brackets and wires are involved. In review, clinical studies and the analysis of laboratory findings support the view that, in orthodontic practice, resistance to sliding has little to do with friction and instead is largely a binding-and-release phenomenon. Interestingly, resistance to sliding is about the same with both conventional and self-ligating brackets.[39]

Space closure with Angle and Tweed edgewise mechanics requires closing loops that involve the use of rectangular steel arch wires. Many clinicians prefer to use edgewise mechanics, because they provide for friction-free tooth movement. Significant disadvantages of this approach include (1) the time required to bend the wires; (2) the need to apply heavy forces across the extraction spaces; and (3) the fact that only a short time range of activation is possible, thus requiring frequent patient appointments. Since the 1990s, sliding mechanics have been used as part of various attempts to decrease the amount of force that is required to close space. The sliding technique for space closure generally uses either elastomeric chains or modules in coil springs. The elastomeric chain was introduced during the 1960s. It has the advantage of being inexpensive, but it suffers from rapid force decay of between 50% and 70% during the first 24 hours. The introduction of space-closing coil springs, which were originally made of stainless steel and cobalt–chromium–nickel alloys and more recently replaced by nickel–titanium springs, have less force decay as compared with elastomeric springs (8% to 20% versus 50% to 70%). Advocates for space closure with both techniques can be found. Inexpensive elastomeric products are still often preferred, because they are generally effective.

In an ideal world, orthodontic treatment would require no compliance from the patient. Unfortunately, removable anchorage devices (e.g., cervical and reverse pull headgear, intermaxillary elastics) are still required with various orthodontic maneuvers. The clinical use of intermaxillary traction with nickel titanium coil spring-and-piston cylinders that are attached to a fixed appliance and used to hold the mandible in a postured position are theoretically interesting, but they involve frequent breakage problems. The use of TADs (e.g., non-osseointegrated titanium micro-screws or titanium plates held in place with screws) that are placed directly into alveolar bone are now used for anchorage; these often circumvent the need for devices that require patient compliance. There is more information about TADs later in this chapter.

Removable Appliances Used in Orthodontic Treatment

The use of removable appliances to guide tooth movement has a long history and persuasive clinical advocates. There have been periods of intense use followed by waning interest. During the late 19th and early 20th centuries, the use of fixed appliances was limited by available materials, the need for labor-intensive "chair time," and an incomplete mechanical understanding of their potential by most clinicians. Removable orthodontic appliances have several immediate advantages, including that they can be fabricated in a laboratory (thereby reducing "chair time" for both the patient and the dentist) and that they can be removed at socially sensitive times or to make oral hygiene easier. Removable appliances that are used for the movement of teeth have disadvantages, including their dependence on consistent patient compliance. They are difficult to construct, thus making precise complex tooth movements problematic. Even with excellent patient compliance, carrying out complex tooth movement remains an issue.

During the early 1900s, removable upper and lower arch appliances used to produce the desired tooth movement were often made of heavy gold wires as a framework from which lighter gold finger springs were placed. The first molars were banded, and wire ligatures were used to tie in heavy labial and lingual arch wires. Interestingly, the use of removable appliances for the movement of teeth was favored in Europe during the first half of the 20th century. This was primarily for economic reasons, and there was a lack of a strong clinical advocate for fixed appliances on that side of the Atlantic. During the same time frame, Edward Angle's profound influence on clinicians in the United States encouraged the preferred use of the edgewise fixed appliance system.

Functional appliances represent a second category of removable design (although they may also be fixed). They are constructed primarily with the hope of changing the position of the mandible (i.e., to hold the lower jaw open and to posture it forward) as well as to limit or enhance the eruption of maxillary molars. The history of functional appliances can be traced back to the mid 1800s, when Norman Kingsley introduced the "bite-jump" appliance (1879).[114] The "monobloc," which was developed by Robin in the United States during the early 1900s, was followed by the "activator," which was developed in Norway by Andresen during the 1920s; both of these devices became widely accepted. Harvold reintroduced removable functional appliances to North American orthodontists during the 1960s, around the same time that the use of fixed appliances finally began to catch on throughout Europe. Harvold's animal model studies confirmed that mandibular posture did in fact affect maxillomandibular growth[92-97] (see

Chapter 4). This led to a belief that functional appliances could be used to "alter back" abnormal jaw growth tendencies. During the 1970s, the Frankel regulator by Rolf Frankel of East Germany popularized the concept of a tissue-borne functional appliance. By the 1980s, William Clark of Scotland introduced the Twin Block, which is a two-piece, tooth-borne appliance. The Twin Block was easier to wear than the Frankel regulator, and it was designed to accomplish the same objectives. Pancherz then popularized the Herbst fixed functional appliance during the 1980s, because it circumvented the problem of patient compliance. This appliance was originally developed by Emil Herbst at the beginning of the 20th century. Proffit has stated that, despite continued strong advocates of functional appliances, *"the results of human clinical trials and retrospective analysis have not confirmed sufficient success with the use of functional appliances to make them mainstay treatment."*[210] Although there is limited evidence-based research to support functional appliances, their continued use in everyday orthodontic practice remains a reality.

Siara-Olds and colleagues recently completed a prospective, randomized, controlled clinical study to assess the early and long-term treatment outcomes of tooth-borne functional appliances.[201] They tested the use of four different functional appliances in a treatment group, and they also followed a group of untreated control subjects with Class II malocclusions. The treatment group (n = 80) was subdivided evenly into four subgroups in accordance with the type of functional appliance being used: the Bionator (n = 20); the Herbst fixed functional appliance (n = 20); the Twin Block (n = 20); and the mandibular anterior repositioning appliance (n = 20). The functional appliance treatment was carried out on individuals with Class II malocclusions who were between the ages of 8 and 12 years. Each randomized Class II malocclusion subject received comprehensive orthodontic treatment with bands and brackets to complete their treatment after the use of the specific functional appliance. The investigators compared lateral cephalometric radiographs that were taken at standard intervals (i.e., before treatment, after functional appliance therapy, and after the completion of comprehensive orthodontics). The four subgroups were also compared with an untreated control group who had similar Class II malocclusions who were not treated with functional appliances, bands, or brackets. *The results of the study confirmed that the use of the functional appliances did not alter long-term mandibular growth patterns as compared with the results seen among the control subjects with Class II malocclusions.* Interestingly, the use of a functional appliance in combination with bands and brackets did demonstrate effects, including the following: (1) the restriction of maxillary horizontal growth; (2) the creation of a steeper occlusal plane (with the Herbst and mandibular anterior repositioning appliances); and (3) the steepening of the mandibular plane angle (i.e., clockwise rotation) with the labial version of the mandibular incisors with the Twin Block appliance.[201] In review, the study by Siara-Olds, et al. confirms that functional appliances for the purpose of correcting micrognathia have negligible impact on the growth potential of the mandible long term.

A third category of removable appliances are used for the retention of the achieved orthodontic results. A spectrum of *retention appliance* designs are used in everyday orthodontic practice. With regard to the issue of retention, Melsen stated the following: "We [orthodontists] deliver the product, but the final result, as when you buy a car, depends on life-long retention and life-long maintenance. Other than diamonds, everything has to be maintained; true stability only occurs post mortem."[142]

We can also add *Invisalign,* which is a product that involves a series of removable clear aligners, as a fourth category to the list of removable orthodontic appliances. It is a method that is used for the purpose of orthodontic tooth movement. Its current level of popularity is at least partially the result of an effective worldwide marketing campaign. Clinical judgment is required to determine when this option is an appropriate form of treatment for the correction of specific—but limited—patterns of malocclusion. Nevertheless, as of 2013, it is estimated that approximately 2 million individuals have completed or are currently receiving Invisalign treatment.

Accelerated Osteogenic Orthodontics

Finding a technique that enhances the speed of orthodontic tooth movement without causing damage has been an objective of clinicians for more than 100 years. Attempts to modify the balance between resorption and deposition and to bypass the waiting time for the alveolar cortex to resorb and thus move the teeth faster without causing irreversible damage to the periodontium has been the focus of much research over the years.[28,29,49,78,79,81,90,101,200,217,218,234] Corticotomy, which is the intentional injury of the cortical bone, was described in the mid 1800s as a surgical approach to correct malocclusion. Osteotomies into the cortical alveolar bone were made, and then the teeth were splinted into new positions. This concept received renewed attention when Kole published a series of clinical articles describing a different approach to the treatment of orthodontic patients.[116,117] In 1975, Duker used a dog model to demonstrate rapid segmental alveolar movement after corticotomy.[68] In 1986, Anholm and colleagues also described corticotomy-facilitated orthodontics in clinical practice.[17] William and Thomas Wilcko further modified the protocol for corticotomy-facilitated orthodontics; they trademarked their technique in 1998.[230,231] That same year, the Wilcko brothers received an endorsement for their technique from the American Academy of Periodontics. Their technique involves elevating a full-thickness mucosal flap off of the alveolar plate (either labial or lingual/palatal) directly over the teeth to be moved. They then place corticotomies (perforations) through the alveolar bone adjacent to the teeth

to be moved with the use of a burr on a handpiece. The Wilckos also recommend placing bone graft material over the surgical perforations in the cortical plate to improve alveolar volume. They then replace the mucosal flap into its anatomic location with sutures. They further claim that the technique enhances difficult tooth movement (i.e., molar intrusion) and that it can provide relative anchorage (i.e., a corticotomy limited to the anterior region will provide relative anchorage from the posterior teeth). The theory behind this technique is that injury to the bone (i.e., the cortical perforations) creates a "regional acceleratory phenomenon."[230] As a result, the body rapidly sends cells to the site to heal the injured bone. This surge in cellular healing activity is thought to promote faster tooth movement. The Wilckos called their technique *accelerated osteogenic orthodontics.*[230]

The animal research by Lino and colleagues[130] and the experimental study completed by Sebaoun and colleagues[197] describe a plausible biologic explanation for the greater speed of tooth movement that is seen with these techniques. **Lino's group** used adult beagle dogs (n = 12). The mandibular right and left first premolars were to be moved mesially with the use of a calibrated spring that attached to the mandibular canines. On one side of each mandible, a flap was elevated, and holes were placed in the alveolar bone (corticotomies) to create a regional acceleratory phenomenon. No corticotomy was performed on the opposite (control) side. The PDL on the mesial (compression) side of each premolar was evaluated histologically at weeks 1, 2, 4, and 8. In addition, the amount of mesial bicuspid tooth movement on each side (i.e., the experimental side versus the control side) was compared at the 8-week interval. Histologic comparisons of the two sides showed very distinct differences. At 1 week, bicuspid tooth compression produced a typical hyalinization of the PDL on both sides. "Hyaline formation" within the PDL, which is referred to as a "sterile necrosis," occurs in response to compressive forces. This is the expected response when significant compressive forces are produced in the PDL. It is known that this sterile necrosis interferes with bone resorption; thus, at the 1-week interval, no tooth movement was experienced on either side. At 2 weeks, hyaline was still present on the control side, so no bone resorption of the tooth socket wall had yet occurred; however, root resorption was evident. At 2 weeks, on the experimental (corticotomy) side, the hyaline had already been removed from the PDL. Presumably, macrophages (the presence of which had been stimulated by the regional acceleratory phenomenon) were in place very early to perform this removal and thus, in the process, no root resorption occurred. At 4 and 8 weeks after the initiation of treatment on the control (non-corticotomy) side, the hyaline had finally been removed and the alveolar bone resorption had begun, thereby allowing mesial bicuspid tooth movement to proceed. During this waiting period, extensive root resorption had occurred on the control side. Interestingly, at the 4- and 8-week post-treatment intervals on the experimental (corticotomy) side, there was no hyaline present in the periodontium, the socket wall had appropriately resorbed, and the bicuspid tooth was able to move mesially without root resorption.

In the rat model, **Sebaoun and colleagues** studied the alveolar response to corticotomy as a function of time and proximity to the surgical injury.[197] Maxillary buccal and palatal cortical plates were injured (corticotomy) in healthy adult rats (n = 36) adjacent to the upper left first molars. Twenty-four of the animals were euthanized at 3, 7, and 11 weeks after injury.

Histomorphometric analysis was performed to study alveolar spongiosa and periodontal ligament dynamics. Both catabolic activity and anabolic actions were also measured. A separate group of animals (n = 12) were fed with calcein fluorescent stain. After the same surgical and orthodontic maneuvers, they were processed for non-decalcified fluorescent stain histology. The results of the study demonstrated that, at 3 weeks, the surgical (corticotomy) group had significantly less calcified spongiosa bone surface, greater periodontal ligament surface, higher osteoclast number, and greater lamina dura apposition width. The catabolic activity (i.e., the osteoclast count) and the anabolic activity (i.e., the apposition rate) increased by threefold, the calcified spongiosa bone surface decreased by twofold, and the PDL surface increased by twofold in the corticotomy group. Interestingly, the surgical injury to the alveolus (corticotomy) that induced a significant increase in tissue turnover by week 3 dissipated to a steady state by postoperative week 11. In addition, the impact of the injury (rapid tooth movement) was localized to the area immediately adjacent to the decortication injury. The authors concluded that selective alveolar decortication induced increased turnover of alveolar spongiosa and that the activity was localized. The escalation of demineralization–mineralization dynamics is the likely biologic mechanism that explains the rapid tooth movement that occurs after selective alveolar decortication.

In review, it appears that the completion of a corticotomy of the alveolar process immediately brings macrophages into the field of bony injury.[116] The macrophages are then able to remove the hyaline (necrotic material) from the periodontium more quickly than occurs in a non-corticotomy setting. The early presence of macrophages can explain the rapid degree of bone resorption and minimal root resorption during orthodontic tooth movement that was documented by Lino and colleagues. When Lino's group compared the amount of tooth movement in their experimental and control groups, the teeth on the corticotomy side moved twice as fast as the teeth on the control side. The enhanced tooth movement after corticotomy should continue as long as the surgical site healing remains in progress (only approximately 2 to 3 months). The potential for morbidity to the teeth and periodontium that is associated with the surgical procedure, must be considered in light of any advantage of reduced time to reach treatment objectives.

Temporary Skeletal Anchorage in Orthodontics

TADs that are made of titanium and temporarily fixed into alveolar bone have been shown to provide effective supplemental or "maximum" anchorage for the movement of teeth while avoiding unwanted negative reciprocal responses in the dentition.* Retromolar titanium (dental) implants simply for the purpose of temporary skeletal anchorage to facilitate orthodontic movement of the teeth were first placed by Roberts and colleagues in 1989.[185-187] Wehrbein and Merz placed titanium implants directly into the hard palate and then tied the molar teeth to them.[224,225] The purpose of the temporary hard-palate implants was to prevent the movement of the molar teeth that were to be used as direct anchorage for the distal movement of anterior teeth into bicuspid extraction sites. Standard titanium bone fixation plates (i.e., mini-plates) were next used as TADs. The mini-plates were fixed to the zygomatic buttress with titanium screws. The end of the titanium plate then perforated through the oral mucosa to provide a point of attachment for orthodontic wires, springs, coils, and elastics.

Mini-plates and mini-screws made of titanium alloy are becoming a frequent temporary source of skeletal anchorage (i.e., TADs) for orthodontic tooth movement. Advantages of these TADs include being relatively simple to place, providing proximity for orthodontic attachments, allowing for immediate loading, requiring no laboratory work, not being socially embarrassing for the patient to use, and being relatively low in cost. Alternatively, TAD use may be complicated by early "loosening" or injury to the teeth and the periodontium. Depending on their location of placement, TADs may also provide vector challenges for accomplishing the task at hand. Although the clinical role of TADs in everyday orthodontic practice has not yet been fully clarified, there are potential applications for a wide spectrum of purposes, including the following:

- The retraction and realignment of the anterior teeth without the need for posterior support (anchorage)
- The closing of edentulous spaces after extraction
- The correction of the midline in patients with missing posterior teeth
- The reestablishment of proper molar positions (i.e., uprighting tipped teeth) for use as abutments
- The intrusion and extrusion of teeth (e.g., to intrude maxillary molars in an attempt to close anterior open bites)
- The protraction and retraction of teeth
- The stabilization of teeth that have reduced alveolar bone support
- The application of orthopedic traction to the maxilla or mandible in the growing individual in an attempts to alter jaw growth

Conclusions

Current problems in clinical orthodontics are no longer a matter of which attachments or mechanical approaches to use. Of greater importance is the basic treatment philosophy related to combined clinical efforts for the achievement of long-term dental health, enhanced facial aesthetics, and an improved airway. The occlusion observed in each individual is greatly influenced by baseline jaw relationships as well as by daily masticatory and airway function. For these reasons, the physiologic orthodontic movement of teeth has limits and should remain within a biologic envelope. With treatment now being rendered to children, adolescents, and adults of all ages, a coordinated comprehensive interdisciplinary approach to care is more important than ever.

Periodontal Considerations in the Evaluation and Treatment of Dentofacial Deformities

JEFFREY C. POSNICK, DMD, MD

- Teeth
- The Tissues of the Periodontium
- Aging and the Periodontium
- Etiology of Periodontal Disease
- Assessing the Individual's Biologic and Anatomic Risk Factors
- Potential Detrimental Effects of Orthodontic "Camouflage" Maneuvers on the Periodontium
- Establishing a Healthy Periodontium and Periodontal Therapeutics
- Adult Orthodontic Treatment
- Conclusions

Degeneration of the periodontium is likely to accelerate in the presence of specific intrinsic biologic factors (i.e., the individual's biotype or predisposition of the periodontium), including the following: (1) a baseline jaw discrepancy with malocclusion; (2) the crowding of the teeth (i.e., the dental roots) within limited alveolar bone; (3) a forced mouth-breathing pattern in combination with a limited ability to close the lips together (i.e., inadequate incisor coverage) caused by anterior skeletal vertical (height) excess; and (4) an inadequate amount of attached gingiva at the clinical crown interface of the teeth. When attempting to achieve a favorable alignment of the teeth in each arch as well as improved occlusion through orthodontic maneuvers, these factors should be considered. Additional compounding factors that may also negatively affect the periodontium include the following: (1) active infection or inflammation of the periodontium; (2) non-biologic restorations at the dental–gingival interface; (3) para-occlusal habits (e.g., bruxism, clenching); (4) the use of medications that effect the saliva (e.g., antipsychotics); (5) local toxins (e.g., nicotine); (6) poor oral hygiene; and (7) the effects of age.

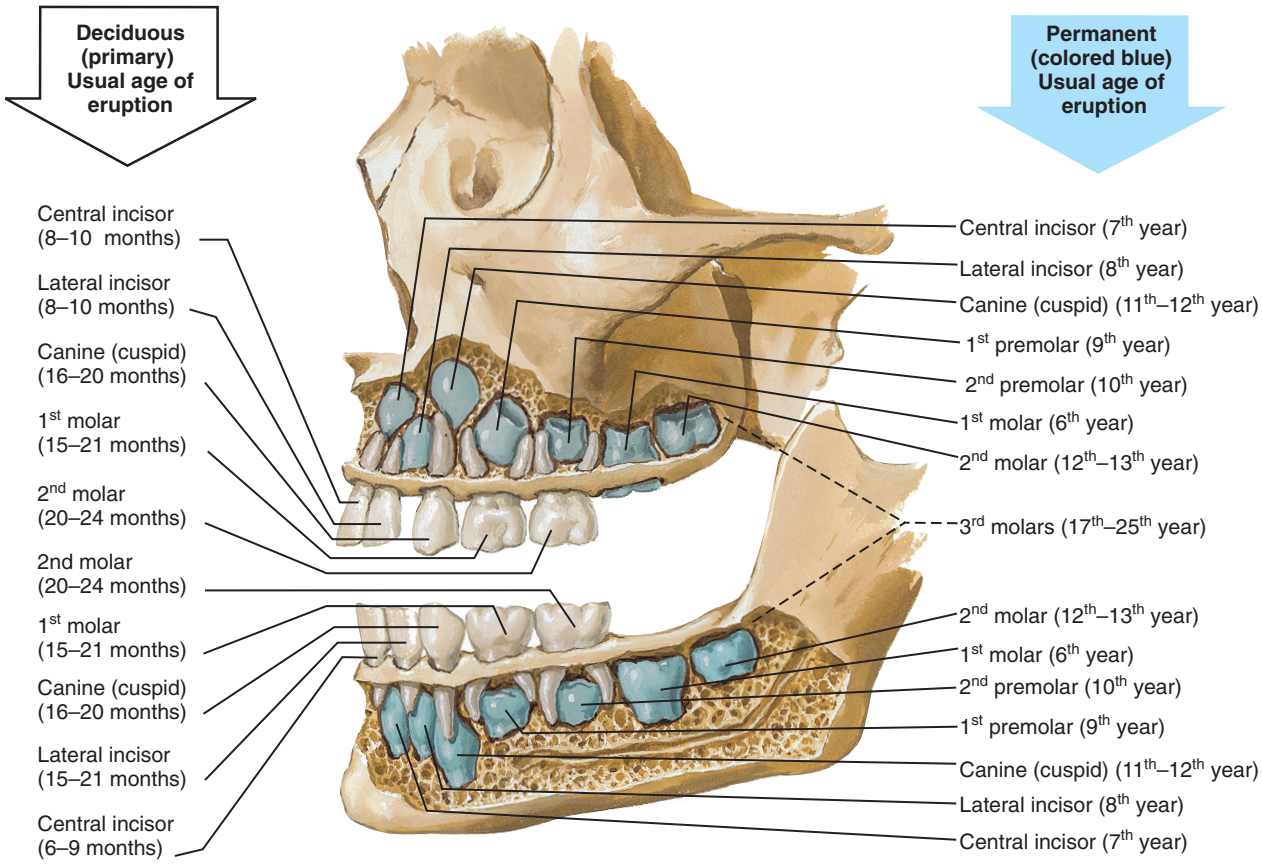
Teeth

General Information (Fig. 6-1)

Teeth are hard structures that are made up of an enamel-covered surface called the *crown* and a cementum-covered surface called the *root.* The root of the tooth is attached to the alveolar bone (i.e., the jaw bone) via the periodontal ligament (PDL). Teeth are primarily used for chewing, speech, and swallowing. The maxillary and mandibular arches both contain teeth. Humans have two sets of teeth during their lifetimes: the deciduous teeth, which are also known as the *primary dentition,* and the permanent teeth, which are known as the *secondary dentition.* Between the ages of 6 and 12 years, there is a mixed dentition during which both the primary and permanent teeth are present in the oral cavity at the same time.

There are 20 total deciduous teeth, which are composed of two incisors, one canine, and two molars in each of the four quadrants of the oral cavity. Under normal circumstances, no deciduous teeth are present at birth. Generally, by the third year of life, all 20 deciduous teeth have erupted.

There are 32 total permanent teeth, which are composed of two incisors, one canine, two premolars, and three molars in each of the four quadrants of the oral cavity. Usually the first permanent tooth to erupt into the oral cavity is the mandibular first molar. The first molar typically erupts at approximately 6 years of age. The molar erupts distal to the primary dentition and behind the second primary molar. The primary teeth eventually are replaced by the permanent teeth. If a permanent tooth is congenitally absent, then the primary tooth typically remains in the arch for an extended period of time.



• **Figure 6-1** Illustration of a sagittal view of a maxilla and mandible with the outer cortex of bone removed to demonstrate a fully erupted deciduous (primary) dentition and the location of the developing permanent tooth buds. Also indicated on the illustration are the usual ages of dental eruption for each tooth of both the deciduous and the permanent dentitions. *From* www.netterimages.com. *© Elsevier Inc. All rights reserved.*

Descriptions of the Surfaces of the Teeth (Fig. 6-2)

Labial: The surface of the anterior teeth that is closest to the lip
Buccal: The surface of the posterior teeth that is closest to the cheek
Facial: A synonym for *labial* or *buccal*
Lingual: Opposite the tongue in the mandibular arch and opposite the hard palate in the maxillary arch
Mesial: Closest to the midline of the dental arch
Distal: Farthest from the midline of the dental arch
Incisal: The cutting edge of the anterior teeth
Occlusal: Used for chewing on the posterior teeth

Basic Anatomy of a Tooth (Fig. 6-3)

Crown

- Anatomic crown: The portion of the tooth that has a surface of enamel.
- Clinical crown: The portion of the tooth that is exposed within the oral cavity.

Root

- Anatomic root: The portion of the tooth that has a surface of cementum.
- Clinical root: The portion of the tooth that is housed within the maxilla or mandible and that is not exposed to the oral cavity.

Apex of the Root

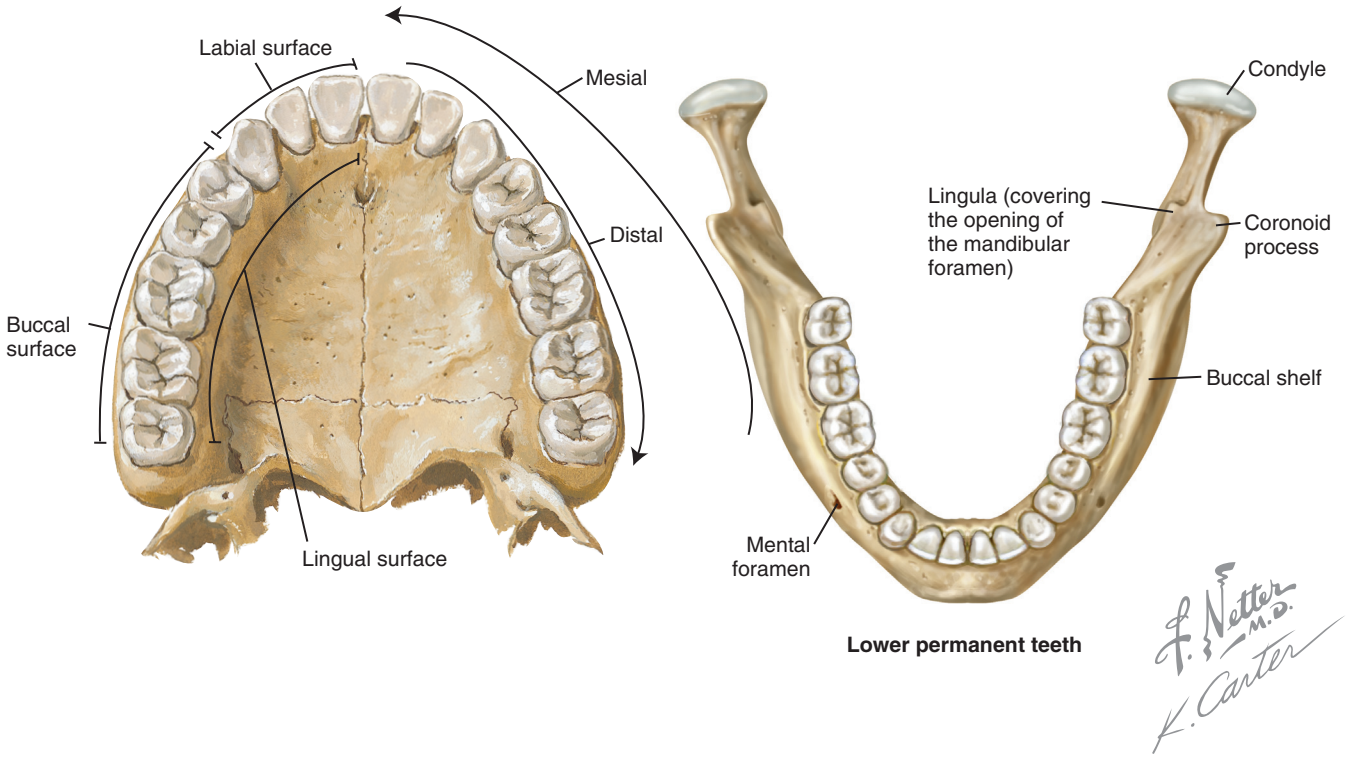
- The apex of the root is the end tip of the root, which is also the location of a small aperture at the point of each root. The aperture provides an entrance for the neurovascular connective tissue into the pulp cavity.

Cervical Line

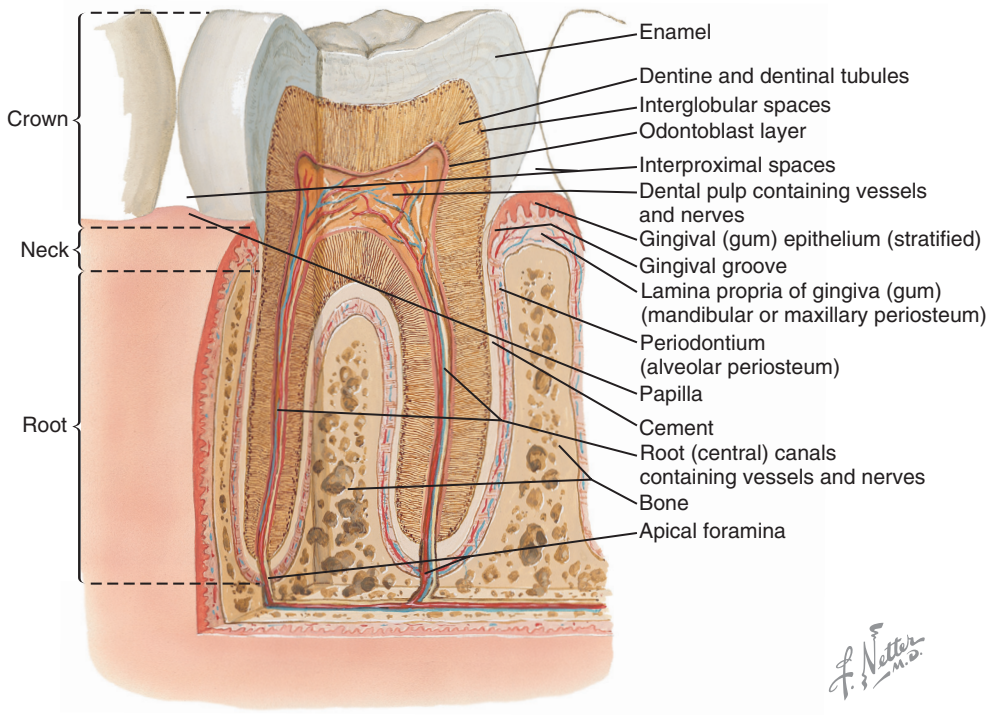
- The cervical line is the anatomic demarcation between the crown and the root. It is often called the *cementoenamel junction* (CEJ).

Enamel

- The enamel is the hard, shiny surface of the anatomic crown as well as the hardest portion of the tooth. It is



• **Figure 6-2** Illustrations of the fully erupted permanent dentition in the maxilla and mandible. The palate and the lingual view illustration are used to define terminology for the surfaces of a tooth. *From* www.netterimages.com. *© Elsevier Inc. All rights reserved.*



• **Figure 6-3** Illustration of a cross-sectional view through a permanent molar and the associated alveolus. Pertinent anatomic terminology is labeled. *From* www.netterimages.com. *© Elsevier Inc. All rights reserved.*

made of small hexagonal rods called *enamel prisms* that are parallel to one another.
- Enamel is 96% inorganic minerals by weight and 4% organic matter and water by weight.

Cementum

- The cementum is a thin, dull layer on the surface of the anatomic root. The cementum is similar in structure and chemical composition to bone. With age, cementum increases in thickness.
- Cementum is 45% to 50% inorganic material by weight and 50% to 55% organic matter and water by weight.

Dentin

- The dentin is the hard tissue that underlies both the enamel and the cementum and that constitutes the major portion of the tooth. Dentin is a modification of osseous tissue. It is composed of a number of dental tubules (small, wavy, and branching tubes) that are located in a dense matrix.
- Dentin is 70% inorganic material by weight, 20% organic material, and 10% water.

Cusp

- A cusp is an elevation on the occlusal surface of the molars and the premolars that makes up a divisional part of the tooth. The incisal edge of the canines is referred to as the cusp, and it is used for prehension (i.e., the grasping and tearing) of food.

Pulp Cavity

- The pulp cavity contains the dental pulp (neurovascular connective tissue). The pulp is separated into the pulp chamber, which is located in the coronal portion of the tooth, and the pulp canal, which is located in the root portion of the tooth.

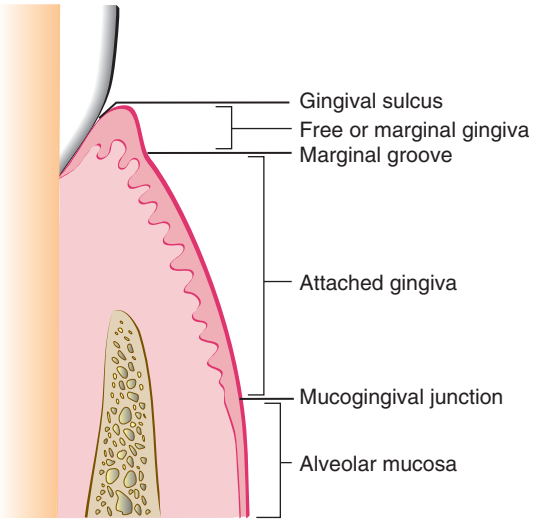
Cingulum

- The cingulum is a convex elevation that is located on the lingual surface of the crowns of anterior teeth just incisal to the CEJ.

The Tissues of the Periodontium

The periodontium includes the investing and supporting tissues of the teeth. It consists of two parts: the *attachment apparatus* (the cementum, the alveolar bone, and the intervening PDL) and the *dentogingival unit* (the gingival connective tissue that inserts into the supracrestal cementum and the sulcular and junctional epithelium as well as the latter's attachment to enamel) (Fig. 6-4). The cementum covers the root surfaces. It serves as the attachment for the fibers of the PDL to the tooth as does the (cortical) alveolar bone of the alveolar socket. The periodontium is affected by the individual's unique maxillofacial skeletal anatomy, by functional (occlusal) forces, and by degenerative cellular changes that occur with age. The greatest modifier of the periodontium is inflammatory disease.

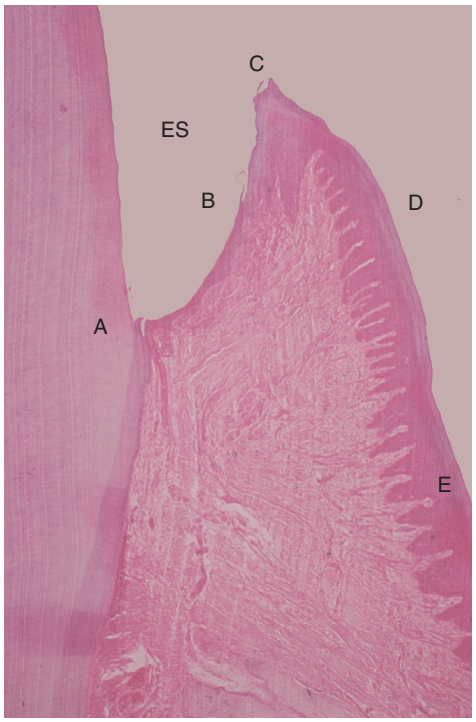
• **Figure 6-4** Intraoral view demonstrating the normal width of attached gingiva in the human permanent dentition. *From Newman MG, Takei HH, Klokkevold PR, Carranza FA:* Carranza's clinical periodontology, *ed 11, St. Louis, 2012, W.B. Saunders Company, Figure 2-3.*



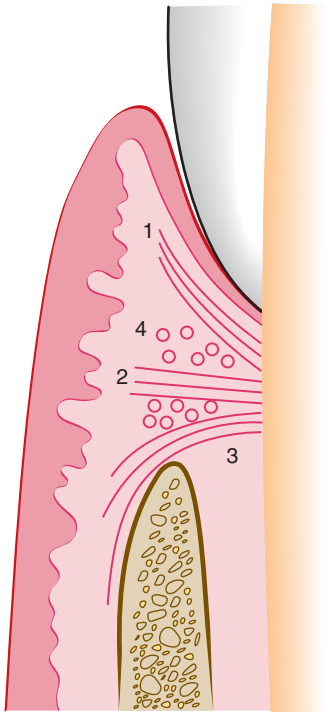
• **Figure 6-5** Diagram showing the anatomic landmarks of the gingiva. *From Newman MG, Takei HH, Klokkevold PR, Carranza FA:* Carranza's clinical periodontology, *ed 11, St. Louis, 2012, W.B. Saunders Company, Figure 2-2.*

The oral epithelium consists of three zones (Figs. 6-5 and 6-6):

1. *Masticatory mucosa (keratinized tissue):* This includes the gingiva, the hard palate, and the dorsal surface of the tongue. The gingiva is a fibrous investing tissue that immediately surrounds and is contiguous with its PDL and with the mucosal tissues of the mouth. Keratinized epithelium also covers the hard palate.
   - *Attached gingiva*: This is the portion of the gingiva that is firm, dense, stippled, and tightly bound to the underlying periosteum, tooth, and bone.
   - *Free gingiva*: This part of the gingiva surrounds the tooth and is not directly attached to the tooth surface.



• **Figure 6-6** Histologic appearance of healthy gingiva. A photomicrograph of a demineralized tooth with the gingival tissues in situ (hematoxylin and eosin stain, low magnification). The amelocemental junction *(A)* and the enamel space *(ES)* are shown. Gingival health is characterized by the organization of the epithelium into distinct zones: the junctional epithelium *(A* to *B)*, the sulcular epithelium *(B* to *C)*, the free gingiva *(C* to *D)*, and the attached gingiva *(D* to *E)*. The gingival connective tissue is composed of densely packed, organized, and interlacing collagen bundles. There are a few scattered inflammatory cells, but there is no significant inflammatory cell infiltrate. *From Newman MG, Takei HH, Klokkevold PR, Carranza FA:* Carranza's clinical periodontology, *ed 11, St. Louis, 2012, W.B. Saunders Company, Figure 21-1.*



• **Figure 6-7** Diagram of the gingival dental fibers that extend from the cementum *(1)* to the crest of the gingiva, *(2)* to the outer surface, and *(3)* external to the periosteum of the labial plate. Circular fibers *(4)* are shown in cross-section. *From Newman MG, Takei HH, Klokkevold PR, Carranza FA:* Carranza's clinical periodontology, *ed 11, St. Louis, 2012, W.B. Saunders Company, Figure 2-20.*

- *Marginal gingiva*: This is most coronal portion of the gingiva. This term is often used to refer to the free gingiva that forms the wall of the gingival crevice in a normal, healthy mouth.
- *Crevicular (sulcular) epithelium*: This is the nonkeratinized epithelium of the gingival crevice.
- *Junctional epithelium*: This involves a single layer or multiple layers of non-keratinized cells that adhere to the tooth surface at the base of the gingival crevice. This was formerly called the *epithelial attachment.*

2. *Lining mucosa (non-keratinized tissue):* This epithelium makes up the majority of the mucosa of the mouth and is the primary lining of the oral mucosa.
3. *Specialized mucosa:* This is found specifically in the regions of the taste buds on the dorsum of the tongue.

The *gingiva* is the part of the oral mucous membrane that covers the occlusal aspect of the alveolar processes of the jaws and that surrounds the necks of the teeth. The *junctional epithelium* and the *connective tissue attachment* have a characteristic dimension of 2 to 4 mm; this zone of tissue is called the *biologic width.* In general, an individual can only maintain health when the sulcus depth is no more than 3 to 4 mm. Greater depth provides a safe haven for bacteria that cannot be easily removed through normal oral hygiene maneuvers. A lower-than-average alveolar crest level is acceptable as long as it is stable (i.e., not progressive) and the periodontium is free of active disease. On the palatal surface of the teeth, the *attached gingiva* blends with the equally firm and highly keratinized *palatal (masticatory) mucosa.* The *interdental gingiva* occupies the gingival embrasure (i.e., the interproximal space beneath the area of tooth contact). It consists of the facial papilla, the lingual papilla, and the valley-like depression that connects the two in the interproximal contact area, which is called the *col.* In the absence of proximal tooth contact, the gingiva is firmly bound over the interdental bone; it forms a smooth, round surface without a triangular interdental papilla. The connective tissue of the gingiva is densely collagenous, and it contains collagen fiber bundles called *gingival fibers* (Fig. 6-7). When these fiber bundles insert into the tooth's cementum, they are called *Sharpey's fibers,* and they result in the mechanical attachment of the sulcular and supracrestal (i.e., crestal to the alveolar process) gingiva. These fibers are able to withstand masticatory forces without deflection or detachment from the tooth surface. The connective tissue attachments extend from just apical to the *junctional*

epithelium of the *sulcular (crevicular) gingiva* to the supracrestal cementum of the root.

The junctional epithelium is connected to the tooth surface via a hemidesmosomal adhesion. These two ectodermal tissues and their interface act to block the flow of toxic chemicals and organisms from the oral cavity into the body.

The *gingival sulcus* contains a fluid that is derived from the gingival connective tissue and that flows through the thin epithelium of the sulcular wall. The gingival fluid is cleansing, and it contains sticky plasma proteins to increase the adhesion of the epithelial attachment to the tooth. The fluid possesses antimicrobial properties, and it is active in its defense of the gingiva. It may also serve as a medium for bacterial growth, which contributes to the formation of dental plaque and calculus. The amount of gingival fluid (exudate) increases with inflammation. The composition of gingival fluid has many similarities to that of blood serum.

The *attached gingiva* is continuous with the *marginal gingiva,* and it consists of stratified squamous epithelium and an underlying connective tissue stroma. The superficial layer is keratinized, parakeratinized, or both. The connective tissue of the gingiva is known as the *lamina propria.* It is densely collagenous, with few elastic fibers, and it consists of two layers: a papillary layer next to the epithelium and a reticular layer next to the periosteum of the alveolar process.

Each *interdental papilla* consists of a central core of densely collagenous connective tissue covered by stratified squamous epithelium. The facial and lingual papillae are joined with the connective tissue of the col and the stratified squamous epithelium from the adjacent interdental papillae. The epithelium of the col is not keratinized and therefore more susceptible to inflammation. The shape of the interdental gingival papillae correlates with the shape of the teeth and the embrasures. The interdental papillae may be broad or narrow, depending on dental positioning and points of connection.

In a normal physiologic state, the gingiva is firm and resilient. With the exception of the movable free margins (i.e., the marginal gingiva), it is tightly bound to the underlying bone. This is the result of the collagenous nature of the lamina propria and its integration with the periosteum of the alveolar process. The visual stippling that is seen when viewing the gingival surface represents the pulling of the superficial gingival layer by the tight connective tissue attachments to the underlying alveolar process.

The Periodontal Ligament

The *PDL* is the connective tissue structure that surrounds the root and that connects the root with the bone in the tooth socket. It is continuous with the connective tissue of the gingiva, and it communicates with the bone through vascular channels. The principal fibers of the PDL are collagenous organized bundles that insert into the cementum on one side and into the bone on the other side; they are called *Sharpey's fibers.* Cellular elements of the PDL include fibroblasts, endothelial cells, cementoblasts, osteoblasts, osteoclasts, tissue macrophages, and stratified epithelial cells. The PDL has physical, formative, nutritional, and sensory functions. These include the physical functions of the transmission of occlusal forces to the bone, the attachment of the teeth to the bone, the maintenance of the gingival tissues in relationship to the teeth, the resistance to the impact of occlusal forces, and the protection of the vessels and nerves from injury by mechanical forces. Destruction of the PDL and the alveolar bone by disease or injury disrupts the balance between the periodontium and the occlusal forces. The PDL supplies nutrients to the cementum, the bone, and the gingiva through the blood vessels; it also provides lymphatic drainage to the same structures. The innervation of the PDL provides proprioception and tactile sensitivity. The PDL includes transseptal, alveolar–crestal, oblique, and apical oriented fibers.

Cementum

Cementum is the calcified mesenchymal tissue that forms the outer covering of the tooth root. There are two types of cementum: acellular and cellular. Both consist of a calcified interfibrillar matrix and collagen fibrils. The cellular type contains cementocytes in individual spaces (lacunae) that allow for communication with each other through a system of canaliculi. There are two types of collagen fibers. The first type is Sharpey's fibers, which are the principal fibers of the PDL and which are formed by fibroblasts. The second group of fibers is thought to be produced by the cementoblasts and to form an interfibrillar substance. The distribution of acellular and cellular cementum varies. The coronal half of the root is usually covered by the acellular type of cementum, whereas the cellular cementum is more common in the apical half of the root. The inorganic content of cementum includes hydroxyapatite, a carbohydrate–protein complex, and acid mucopolysaccharides.

The relationship of the interface between the cementum and the enamel at the crown–root interface varies. Cementum overlaps the enamel in about two thirds of cases. In the other third, there is an edge-to-edge arrangement in which a small percentage of the cementum and the enamel fail to meet.

When cementum resorption occurs, it is seen microscopically as concavities on the root surface. Multinucleated giant cells and large mononuclear macrophages are generally found adjacent to the cementum that is undergoing active resorption. The resorptive process may extend into the underlying dentin and even into the pulp. In a physiologic setting, embedded fibers of the PDL reestablish a functional relationship in the new cementum. Cementum repair requires the presence of viable connective tissue. If epithelium proliferates into an area of cementum, then resorption rather than repair will likely take place. Fusion of the cementum and the alveolar bone with obliteration of

the PDL is termed *ankylosis.* When ankylosis does occur, it generally happens after chronic periapical inflammation, tooth replantation, or significant occlusal trauma. It may also represent a congenital failure of eruption.

The *anatomic root* is the portion of the tooth that is normally covered by cementum. The anatomic crown is the portion of the tooth that is covered by enamel. The *clinical crown* is the part of the tooth that includes the anatomic part of the crown and the part of the root that has been denuded of periodontium and that is visible in the oral cavity. The clinical root is that portion of the tooth that remains covered by periodontal tissues (i.e., the PDL, the cementum, and the gingiva). Exposure of the root via the apical migration of the gingiva margin is called *gingival recession.* Exposure of the root to the oral cavity via the apical migration of the junctional epithelium without apical migration of the gingival margin results in pocketing. In either case, periodontal degenerative changes result in the permanent exposure of connective tissue (i.e., the dentin and the cementum) to the external environment.

The Alveolar Bone

All parts of the alveolar process serve to support the teeth. Occlusal forces are transmitted through the PDL to the inner wall of the alveolus, which is then supported by the cancellous trabeculae. The cancellous trabeculae in turn are buttressed by the labial and lingual cortical plates. The alveolar process is the bone that supports the tooth socket, and it consists of the following:

- The inner socket wall of thin compact bone (the alveolar bone proper);
- The supporting alveolar medullary bone (the cancellous trabeculae); and
- The facial and lingual plates (compact bone).

The alveolar process consists of calcified matrix with osteocytes that are enclosed within spaces called *lacunae.* The *canaliculi* form an anastomosing system through the intercellular matrix of the bone, which brings oxygen and nutrients to the osteocytes and which removes metabolic waste products. In the cancellous trabeculae, the matrix is arranged in lamellae that are demarcated from each other by prominent cement linings. The *compact alveolar bone* (i.e., the bony lining of the alveolus) consists of closely arranged lamellae and Haversian systems. The principal fibers of the PDL that anchor the tooth in the socket are embedded into the alveolar bone and are referred to as *Sharpey's fibers.* The *socket wall* consists of dense laminated bone. The cancellous portion of the alveolar bone consists of trabeculae, which enclose irregularly shaped marrow spaces that are lined with a layer of thin, flattened ostial cells.

The bony wall of the tooth socket appears radiographically as a thin radiopaque line; it is called the *lamina dura*. The alveolar bone is perforated by numerous channels that contain blood vessels, lymph vessels, and nerves, which link the PDL with the cancellous portion of the alveolar bone. The vascular supply of the bone is derived from blood vessels in the PDL and in the marrow spaces and from small branches of peripheral vessels that penetrate the cortical plates. The interdental septum consists of cancellous bone that is bordered by the socket walls of approximating teeth and the facial and lingual cortical plates.

The mesiodistal angulation of the crest of the interdental septum parallels a line drawn between the CEJs of the approximating teeth. The average distance between the crest of the alveolar bone and the CEJ in the mandibular anterior region in an individual who is periodontally healthy is approximately 1 mm. With disease progression, the distance between the bone ridge and the CEJ increases throughout the mouth.

The alveolar bone contour normally conforms to the prominence of the roots of the teeth, with regions of mild depression in between. The height and thickness of the facial and lingual bony plates are affected by the alignment of the teeth and the angulation of the roots in the bone. For example, in the patient with mandibular deficiency and excessive incisor procumbency, the labial bone may be thin, and apical migration may be seen along the tooth surface. When the mandibular incisor teeth are lingually positioned (i.e., skeletal Class III), the facial bony plate is generally thicker than normal. Another example is seen when the maxillary molar roots are at acute angles to the palatal bone. The effects of the root location and angulation result in recession of the marginal bone.

An isolated area in which a tooth root is denuded of labial cortical bone, the root surface is covered only by periosteum and overlying gingiva, and the marginal bone remains intact is termed *fenestration*. An area of the tooth root in which there is denuded bone and where the root surface is covered only by periosteum where the root denudation extends to the margin is called *dehiscence*. Dehiscences are more common on the labial surface of the lower anterior teeth and on the molars and premolars of the maxilla. Congenital or developmental jaw hypoplasia with dental crowding and trauma from occlusal treatments or orthodontics are common etiologic factors for fenestrations and dehiscences.

Alveolar bone is a structure that is constantly in a state of flux. It is maintained by a delicate balance between bone formation and bone resorption, and it is controlled by local and systemic influences. Bone is resorbed in areas of pressure and deposited in areas of tension. With age and normal occlusal forces, there is a tendency for the mesial migration of the teeth. As a result, the associated alveolar bone is remodeled via resorption and deposition.

The purpose of the alveolar process is to support the teeth both while they are at rest and while they are functioning. Its structure is dependent on the stimulation that it receives from masticatory function, because it undergoes

constant remodeling in response to occlusal forces. When force is applied to a tooth, that force is displaced against the resilient PDL, thereby creating areas of tension and compression. The facial and lingual walls of the tooth socket bend in the direction of the force. When the force is released, the tooth, the PDL, and the bone spring back toward their original positions. In response to these forces, osteoblasts and newly formed osteoid will line the socket in areas of tension, whereas osteoclasts position themselves and resorption occurs in areas of pressure. The bone trabeculae are aligned in the path of the tension and compressive stresses to provide maximum resistance to the occlusal force with the minimum of bone substance. Forces that exceed the adaptive capacity of the bone produce injury. When occlusal forces are increased, the cancellous trabeculae also increase in number and thickness to provide necessary support.

Aging and the Periodontium

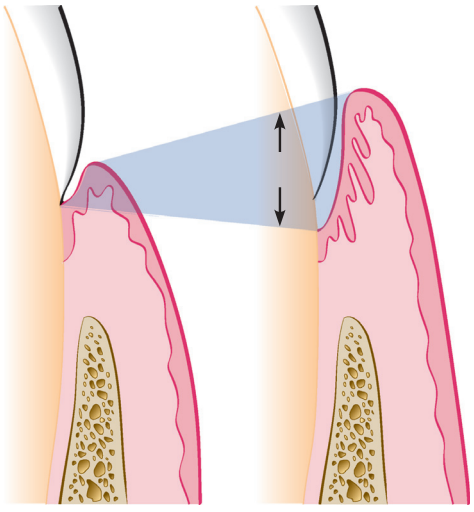
The prevalence of periodontal disease with tissue destruction and the loss of teeth and tooth structure tends to increase with age.[106,155,160,171] Another consequence of age is reduced tissue elasticity through the degeneration of the elastic fibers. Hormonal changes also occur, and these change the local tissue environment. Traditional thinking is that the degenerative gingival changes associated with aging may include recession, diminished keratinization, reduced stippling, decreased connective tissue cellularity, increased intercellular substances, and reduced oxygen consumption. In the PDL, degenerative aging effects are thought to include a decrease in elastic fibers and a decrease in vascularity and mitotic activity. If these effects occur, the ability of the alveolar bone to withstand occlusal forces is diminished. Frequent changes in tooth structure with age are seen, including occlusal wear with a loss of enamel substance that reduces cusp height and inclination. The degree of attrition is influenced by the masticatory musculature, the consistency of the food eaten, and occlusal factors and habits such as clenching and bruxism. A degree of continued tooth eruption usually occurs as teeth wear. As a result, the clinical crown may become longer, which creates further leverage on the bone with masticatory forces. An opposing factor is the fact that the clinical crowns are simultaneously reduced through attrition, often with an equilibrium or balance being present between the teeth and their bony support. The wear of the teeth along the proximal surfaces may also occur, which results in mesial migration. On average, proximal wear reduces the anteroposterior length of the dental arch by approximately 5 mm by the age of 40 years and by twice that by life's end. When chronic periodontal disease is added to physiologic degenerative aging, the destructive response of the periodontium is exacerbated. There may be continued gingival recession, attrition, and the reduction of alveolar bone height as a result of a combination of these factors.[31]

Etiology of Periodontal Disease

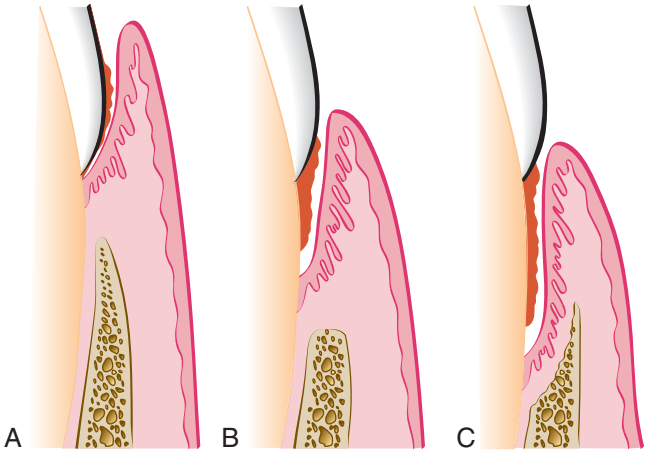
Gingivitis and Periodontitis

Inflammation of the gingiva, which is also known as *gingivitis,* is the most common form of gingival disease (Figs. 6-8 through 6-12).[1,19,177,183,216] This occurs as a result of local irritants, such as the toxins released by the microorganisms related to dental plaque and calculus. Foreign bodies (e.g., orthodontic appliances, irregular dental restorations) may also serve as local irritants as well as plaque traps. The

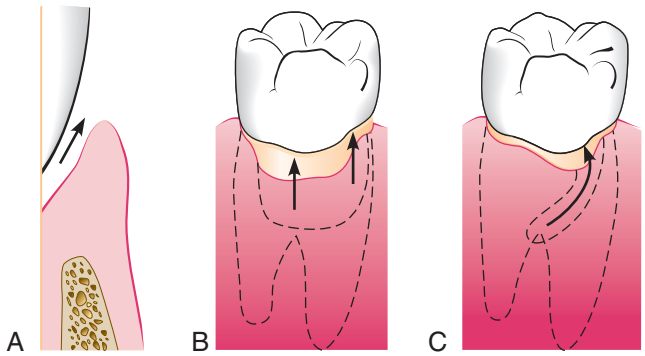
• **Figure 6-8** Photograph of the maxillary anterior dentoalveolar region. Dehiscence of the labial cortical plate of the canine and fenestration of the labial cortical plate of the first premolar are demonstrated. *From Newman MG, Takei HH, Klokkevold PR, Carranza FA:* Carranza's clinical periodontology, *ed 11, St. Louis, 2012, W.B. Saunders Company, Figure 2-60.*



• **Figure 6-9** Illustration of pocket formation that indicates expansion in two directions *(arrows)* from the normal gingival sulcus *(left)* to the periodontal pocket *(right). From Newman MG, Takei HH, Klokkevold PR, Carranza FA:* Carranza's clinical periodontology, *ed 11, St. Louis, 2012, W.B. Saunders Company, Figure 13-1.*

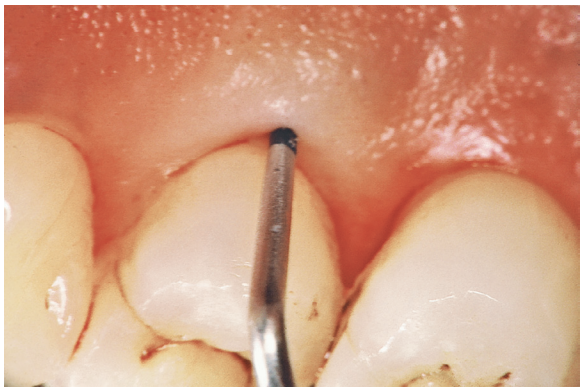


• **Figure 6-10** Different types of periodontal pockets. With a gingival pocket *(A)*, there is no destruction of the supporting periodontal tissues. With a suprabony pocket *(B)*, the base of the pocket is coronal to the level of the underlying bone, and bone loss is horizontal. With an intrabony pocket *(C)*, the base of the pocket is apical to the level of the adjacent bone, and bone loss is vertical. *From Newman MG, Takei HH, Klokkevold PR, Carranza FA:* Carranza's clinical periodontology, *ed 11, St. Louis, 2012, W.B. Saunders Company, Figure 13-2.*



• **Figure 6-11** Classification of pockets according to involved tooth surfaces. **A,** Simple pocket. **B,** Compound pocket. **C,** Complex pocket. *From Newman MG, Takei HH, Klokkevold PR, Carranza FA:* Carranza's clinical periodontology, *ed 11, St. Louis, 2012, W.B. Saunders Company, Figure 13-3.*

inflammation caused by local irritants can result in ulcerative, necrotic, and proliferative changes in the gingival tissues.[29,30,34,99,165,170,221] When there is deepening of the gingival sulcus, there can be injury to the supporting periodontal tissues; this may become an irreversible process. With continued inflammation, hyperplastic changes of the gingiva occur, and the crest of the gingival margin extends toward the crown. Inflammation causes a proliferation of and a change in the quality of the sulcus and the junctional epithelium such that their normal protective nature becomes dysfunctional. The sulcus becomes a pocket; ulceration through the epithelial barrier with exposure of the underlying connective tissue to the oral cavity is a frequent occurrence. The organisms and their toxins are then able to access the exposed connective tissue, which undergoes further pathologic changes.[93,133,135,154,193] As the process continues,



• **Figure 6-12** Probing of a deep periodontal pocket. The entire length of the periodontal probe has been inserted into the base of a pocket in the palatal surface of the first premolar. *From Newman MG, Takei HH, Klokkevold PR, Carranza FA:* Carranza's clinical periodontology, *ed 11, St. Louis, 2012, W.B. Saunders Company, Figure 13-4.*

the epithelial junction may separate from the root, and the pocket will migrate downward. The epithelium of the lateral wall of the pocket proliferates with inflammatory tissue, which results in varying degrees of degeneration and necrosis. Intrabony periodontal pockets are said to be present when the base is apical to the level of the alveolar bone. The extension of inflammation from the margin of the gingiva into the supporting periodontal tissues marks the transition from gingivitis to periodontitis.[6,40,41,107,117,175,200] The essential problem of periodontal disease is the destruction of alveolar bone with a loss of crestal height and PDL destruction. If periodontal disease is left untreated, it will lead to the loosening and loss of the teeth.

Trauma from Occlusion

Occlusal forces affect the condition and structure of the periodontium.[53,54,59,104,129,134,160,181,191,204] To remain structurally and metabolically sound, the PDLs and the alveolar bone require the mechanical stimulation of occlusal forces. When occlusal forces exceed the adaptive capacity of the tissue, injury occurs. The injury that occurs to the periodontium is called *trauma from occlusion,* and it can be classified as either primary or secondary occlusal trauma. *Primary occlusal trauma* occurs when greater-than-normal occlusal forces are placed on teeth with a normal periodontal attachment apparatus (i.e., those that are periodontally stable). *Secondary occlusal trauma* occurs when normal occlusal forces are placed on teeth with compromised periodontal attachment (i.e., those with periodontal disease).

The periodontium attempts to accommodate the functional demands that are placed on it by the masticatory system. The adaptive capacity of the periodontium varies from person to person. The periodontium is influenced by the severity, direction, frequency, and duration of the force that is put on it and the patient's specific anatomy. The principal fibers of the PDL are arranged so that they can best accommodate occlusal forces in the long axis of the

tooth. Forces that are not aligned well with the tooth's load-bearing capacity place increased compression on specific locations of the PDL. This may result in resorption of bone, depending on the extent and duration of the occlusal force. If the trauma is excessive, a destructive change in the periodontium will occur. If the injurious force is relieved rapidly enough, repair rather than destruction will occur. When trauma is combined with active infection, rapid irreversible destruction of the periodontium is more likely. The degree to which these factors interact and cause destruction remains controversial. There is a need for ongoing clinical research to clarify these issues.

Traditional thinking is that trauma from occlusion is caused by alterations in the occlusal forces, the reduced capacity of the periodontium to withstand what would otherwise be considered normal, or both. Malocclusion is a risk factor for occlusal trauma, but damage may also occur in the presence of a "normal" occlusion. *Trauma from occlusion* refers to the tissue injury rather than the specific occlusion. Increased masticatory forces are not traumatic if the periodontium can accommodate them. Trauma from occlusion and inflammation from an infectious or foreign-body process are different pathologic processes that can occur either in isolation or together. Inflammation typically starts in the gingiva and then spreads into the supporting periodontal tissues. Trauma from occlusion causes pathologic change of the attachment apparatus. When this occurs in the presence of inflammatory processes, these two pathogenic factors may act synergistically to cause greater damage to the periodontium than the sum of each factor's singular effect. These combined components are called *co-destructive factors.*

The histopathologic lesion of occlusal trauma is called the *lesion of the attachment apparatus,* and it is characterized by the following:

- Hyaline degeneration of the PDL
- Vascular thrombosis in the PDL
- Necrosis in the PDL
- Frontal and rear "undermining" resorption of the alveolar bone
- Cementum resorption

The lesion of the attachment apparatus can occur and progress rapidly. It is believed that, when the lesion interacts with plaque-induced inflammatory responses, then the loss of the periodontium is likely to be accelerated.

Effects of Orthodontic Appliances and Tooth Movement Forces

Tooth movement during orthodontic therapy is the result of controlled forces placed on the teeth and then transmitted to the PDL. Strong or heavy forces (i.e., forces that far exceed capillary blood pressure) result in the crushing of the PDL on the compression side of the tooth, with local ischemia and degeneration (i.e., hyalinization). Moderate forces that exceed capillary blood pressure result in the compression of the PDL with a delay in bone resorption and the movement of the tooth.[89] Light continuous forces that are less than the capillary blood pressure result in only limited ischemia to the PDL, with gradual bone resorption on the compression side.[174] The patient's age is not a contraindication to orthodontic treatment per se. Interestingly, in the adult, the hyalinized (necrotic) zones are formed more readily on the pressure side of the orthodontically moving tooth; this will temporarily slow tooth movement.[62] The hyalinized zone is soon eliminated with the reorganization of the tissues, first through the resorption of the marrow spaces (thus undermining resorption) and then through the repair of the PDL and finally of the alveolar bone.[172] The anticipated regeneration of the PDL on the compression side and the formation of new bone on the tension side will likely be hampered by the presence of active inflammation in the periodontal tissues (i.e., periodontitis).[169] This pathologic response is dependent on how long the PDL remains compromised. This is the reason why inflammation should be controlled through effective periodontal treatment before orthodontic tooth movement.*

Until the mid 1980s, heavy intermittent orthodontic forces were routinely used, and this required patient visits every 3 to 4 weeks.[176] This allowed the hyalinized fibers to recover before another heavy orthodontic force was applied. Contemporary orthodontics involves the use of light, continuous force. This moves the teeth with less discomfort and more rapidly, and it also allows visits to be spaced at longer intervals.

In a patient with a periodontally compromised dentition and with a baseline loss of alveolar bone, the center of resistance of the involved teeth moves apically.[141,157] The net effect is that the involved teeth are more prone to tipping rather than to bodily movement when orthodontic forces are applied. To achieve improvement in the periodontium, orthodontic treatment requires a combination of light controlled forces as well as the movement of teeth more completely into the alveolar housing. In the presence of active disease, orthodontic therapy should be postponed until effective periodontal treatment is accomplished. This approach to orthodontic tooth movement has been shown to improve any preexisting compromised periodontium.

Interestingly, the orthodontic movement of endodontically treated teeth is not a risk factor to the periodontium, because the response of the PDL is not affected by the pulp. Some studies do indicate that endodontically treated teeth are slightly more prone to root resorption during orthodontic treatment as compared with teeth with normal vitality.

Teeth that are already tipped outside of the cortical plate (e.g., proclined mandibular incisors in the individual with Class II malocclusion) and that are orthodontically

*References 20, 21, 24, 25, 36, 43, 47, 49, 56, 66, 100, 111, 115, 116, 121, 122, 142, 144, 151, 156, 173, 182, 192, 197, 198, 202, 218-220

uprighted into sound alveolar housing are likely to improve in overall periodontal health, even when the gingiva levels remain borderline. Animal studies indicate that, without the presence of plaque, orthodontic forces on the teeth do not in themselves induce gingivitis.[67] In the presence of plaque, however, similar forces can cause angular bone defects and, with tipping or torquing movements, gingival attachment loss (i.e., recession) can occur.[68-70] Clinical studies have demonstrated that, with adequate plaque control, even teeth with longstanding reduced periodontal support can undergo successful tooth movement without further compromise.[63] In patients with no active periodontal disease and with good oral hygiene—and even in adults with reduced but healthy residual periodontium—physiologic orthodontic treatment causes no significant detrimental long-term effects on the periodontal attachment, including the bone levels. Physiologic tooth movement involves light forces and the movement of teeth into (not outside of) alveolar bone.[37-39]

In a cross-sectional study, radiographic crestal bone levels in adults (N = 104) who completed orthodontic treatment at least 10 years previously were shown to be no different than those of matched control subjects (N = 76).[161] In a 2-year post orthodontic study, Trosello and colleagues compared adult women who had multi-banded orthodontic therapy (N = 30) with age-matched (non-orthodontically treated) controls (N = 30).[203] It was found that the orthodontically treated patients had a higher prevalence of root resorption (17% versus 2%), although there was a lower prevalence of mucogingival defects (5% versus 12%). The root resorption differences were most common in the maxillary incisors, followed by the mandibular incisors. It appears that, in adults, when biologically sound orthodontic maneuvers are carried out, minimal detrimental effects on the health of the periodontium occur. In the short term, gingivitis and gingival hyperplasia may occur, but there is no attachment loss or irreversible effects. In the long term, when the teeth are moved into (not out of) the alveolar bone, mild root resorption (i.e., 1.0 to 1.5 mm) may be documented, but attachment loss (i.e., irreversible change) only occurs in areas of active periodontitis.

It is known that *plaque* is the primary etiologic factor of *gingivitis.* A patient's inability to clean adequately around orthodontic devices (e.g., banded teeth, brackets, wires, springs, coils, elastics, plates) will promote plaque accumulation, which can lead to gingival inflammation. Before the extensive use of bonded brackets, overgrowth of anaerobes in the patient's sulcus was typical.[57] Fortunately, the common practice of placing numerous subgingival orthodontic bands in each quadrant has gone by the wayside. Nevertheless, a shift in the subgingival microflora to a more pathogenic population that is similar to what is seen in periodontal disease sites may occur with use of orthodontic devices.[131] Even without banded bracket appliances, an active and diligent oral hygiene program for the patient that includes frequent periodic checkups by an appropriate dentist is required throughout orthodontic treatment.

Dental Restorations: Gingival Interface

The relationship between bacterial plaque accumulation and gingival inflammation has been documented since at least the 1960s.[132] A patient's susceptibility to gingival inflammation is not based solely on the mere quantity of dental plaque but also on the virulence of the resident plaque microorganisms. The bacterial composition of dental plaque is dynamic, and the pathogenicity of each specific organism is subject to change over time. It is a dental dictum that creating a confluent restorative–gingival interface is an important factor that allows patients' oral hygiene efforts to reduce the accumulation of plaque and microorganisms and to decrease—if not eliminate—the resulting gingivitis. For this reason, emphasis should be placed on the marginal integrity of dental restorations; the coronal contour of the restoration; the embrasure and contact; and the marginal location of the restoration. The proper marginal location of a restoration relative to the alveolar bone is thought to be one of the most important parameters for achieving and maintaining long-term gingival health.[92,124-126,139] Similarly, all patients who are undergoing dental therapy should be philosophically taught and technically trained to perform effective plaque-removal practices.

Assessing the Individual's Biologic and Anatomic Risk Factors

Destruction of the periodontium is more likely to occur in the presence of known risk factors. Specific risk factors include 1) infection, 2) primary occlusal trauma, 3) iatrogenic causes, and 4) intrinsic biologic anatomic aspects. The known intrinsic (unique to the individual) biologic anatomic risk factors for periodontal disease may be referred to as the individual's *biotype* (Figs. 6-13 through 6-29). These factors include the following:

- Inadequate attached gingiva surrounding the clinical crowns of the teeth
- Inadequate alveolar bone to house the roots of the full complement of teeth in each arch
- Inadequate nasal airflow with a forced mouth-breathing pattern, often in association with vertical (skeletal) excess and inadequate lip closure, with limited coverage of the incisors and the gingiva
- The effects of malocclusion associated with a jaw deformity

The individual's biotype may pose risk factors for periodontal tissue loss. These risk factors can often be overcome or at least managed through surgical, orthodontic, and dental interventions; meticulous home care; and the avoidance of toxins such as tobacco, certain medications, and certain chemicals.

Text continued on p. 200

• **Figure 6-13** A 50-year-old man was referred by his general dentist to an orthodontist, who then referred the patient for surgical evaluation. The patient had a history of juvenile rheumatoid arthritis with temporomandibular joint involvement. There is condylar erosion with loss of posterior facial height with retrusion and clockwise rotation of the mandible, which resulted in a Class II anterior open-bite malocclusion. Adequate painless vertical mouth opening is present, and no symptomatic temporomandibular disorder is present. Over the years, there has been destruction of the dentition and the periodontal apparatus with a degree of labial bone loss and gingival recession. At referral to this surgeon, the patient had a history that documented heavy snoring, restless sleeping, and daytime somnolence. An attended polysomnogram confirmed a respiratory disturbance index of 10 events per hour. There is intranasal obstruction as a result of septal deviation and inferior turbinate enlargement, a retropositioned palate as a result of maxillary retrusion, and a retropositioned tongue as a result of mandibular retrusion. The soft palate and the tongue are normal with regard to function and size. The patient had previously undergone tonsillectomy. His biologic and anatomic risk factors for periodontal disease include inadequate alveolar bone (i.e., an inadequate alveolar bone/dental root ratio); nasal obstruction and mouth breathing with lip incompetence; and malocclusion with secondary trauma. A comprehensive approach was recommended to address the patient's upper airway and breathing difficulties, his occlusion issues and his long-term dental health, and his facial aesthetics. **A,** Frontal facial and occlusal views before treatment. **B,** Profile facial view and lateral cephalometric radiograph before treatment. **C,** Panorex radiograph before treatment.

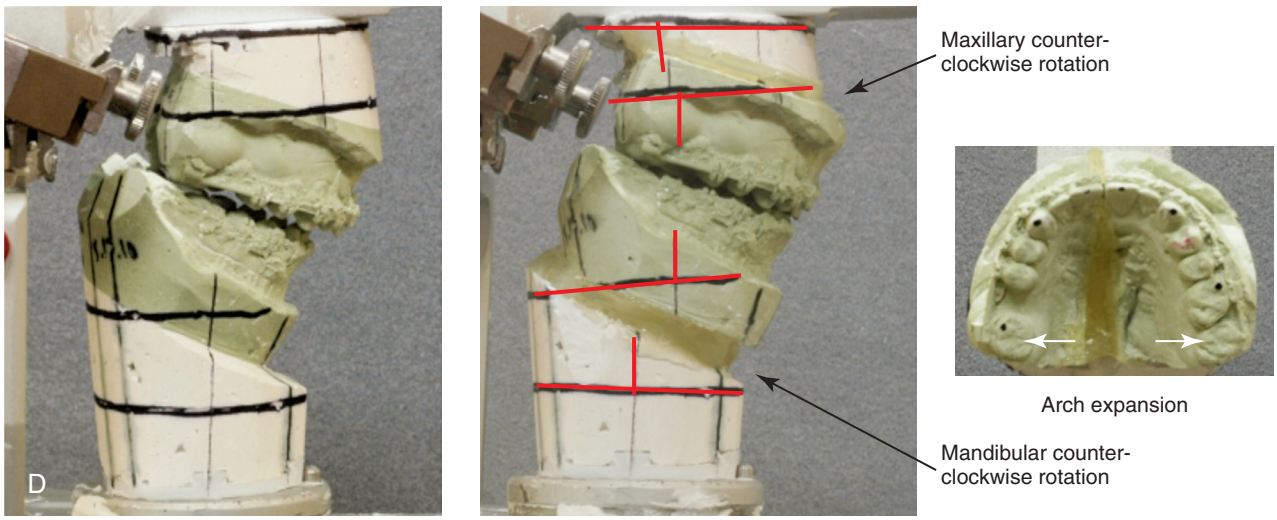
• **Figure 6-14** A 26-year-old college graduate arrived for surgical evaluation. Since the mixed dentition, he was recognized to have a developmental jaw deformity that was characterized by maxillary deficiency in combination with relative mandibular excess. Camouflage orthodontic treatment including four bicuspid extractions was carried out when he was between 12 and 16 years old. A residual Class III negative overjet with an anterior open-bite malocclusion remains. The patient had never been able to breathe well through his nose as a result of septal deviation and inferior turbinate enlargement. Secondary occlusal trauma resulted in the need for root canal therapy and crowns in all four posterior quadrants. There is labial bone loss and gingival recession. A comprehensive dental rehabilitative and reconstructive approach will require periodontal evaluation and treatment followed by orthodontic (dental) decompensation and then jaw and intranasal surgery. **A,** Frontal facial and occlusal views before treatment. **B,** Profile facial view and lateral cephalometric radiograph before treatment. **C,** Panorex radiograph before treatment.

• **Figure 6-15** A 16-year-old boy was born with Stickler syndrome, which is a type II collagen mutation. At the time of his birth, the Pierre-Robin sequence was appreciated. The patient underwent repair of the cleft palate before he was 1 year old. He had positive eye findings and required the treatment of a retinal detachment during his teenage years; a small cataract is being followed. He arrived for the evaluation of a jaw deformity and malocclusion, which were characterized by maxillomandibular deficiency with anterior open-bite malocclusion. This was combined with chronic obstructive nasal breathing and a long face growth pattern. Attempted growth modification and camouflage orthodontics earlier in life were ineffective. There was generalized root deficiency throughout the maxillary and mandibular dentition, likely as a result of the collagenopathy. The patient agreed to an orthodontic and surgical approach. Further orthodontic (dental) decompensation was cautiously carried out as a result of the compromised periodontal apparatus. The procedures included maxillary Le Fort I osteotomy in segments (vertical intrusion, horizontal advancement, and arch expansion); bilateral sagittal split ramus osteotomies (horizontal advancement and limited counterclockwise rotation); osseous genioplasty (vertical shortening and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Frontal views with smile before and after treatment. **B,** Profile views before and after treatment.

Prior to retreatment

Pre surgery

After treatment



• **Figure 6-15, cont'd C,** Occlusal views before retreatment, with orthodontics in progress, and then after treatment. **D,** Articulated dental casts that indicate analytic model planning.

• **Figure 6-16** A woman in her late 20s was born with an isolated cleft palate. She underwent palate repair during infancy, and she later developed a jaw deformity with malocclusion. Attempts to neutralize the occlusion included years of growth modification and orthodontic mechanics with four bicuspid extractions between the ages of 11 and 17 years. The patient was left with generalized labial bone loss and gingival recession, especially of the lower anterior teeth. She presented to this surgeon as an adult with a lifelong history of obstructed nasal breathing. She also had a long face growth pattern that involved the maxilla, the mandible, and the chin and that included excess vertical height and horizontal retrusion of those areas. She underwent periodontic, prosthodontic, orthodontic, surgical, speech pathology, and ear, nose, and throat evaluations, among others. She received periodontal treatment and then orthodontic decompensation. Her surgery included a Le Fort I osteotomy (horizontal advancement and clockwise rotation); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical reduction and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring (see Fig. 34-9). **A,** Frontal facial and occlusal views before retreatment. **B,** Profile view and lateral cephalometric radiograph before retreatment.

• **Figure 6-17** A 21-year-old college graduate arrived for surgical evaluation. The history and examination confirmed lifelong nasal obstruction, lip incompetence, and gummy smile. Further inspection confirmed a long face growth pattern with a Class II anterior open-bite malocclusion. The patient had been under an orthodontist's care since the mixed dentition and throughout her high school years. Growth modification, rapid palatal expansion, and full bracketing with four bicuspid extractions introduced dental compensation but without successful closure of the open bite. Early periodontal deterioration is evident. She agreed to a comprehensive dental and facial rehabilitation approach. Periodontal evaluation and treatment followed by orthodontic (dental) decompensation and then jaw and intranasal surgery were carried out (see Figure 21-5). **A,** Frontal view in repose and occlusal views before retreatment. **B,** Profile view and lateral cephalometric radiograph before retreatment.

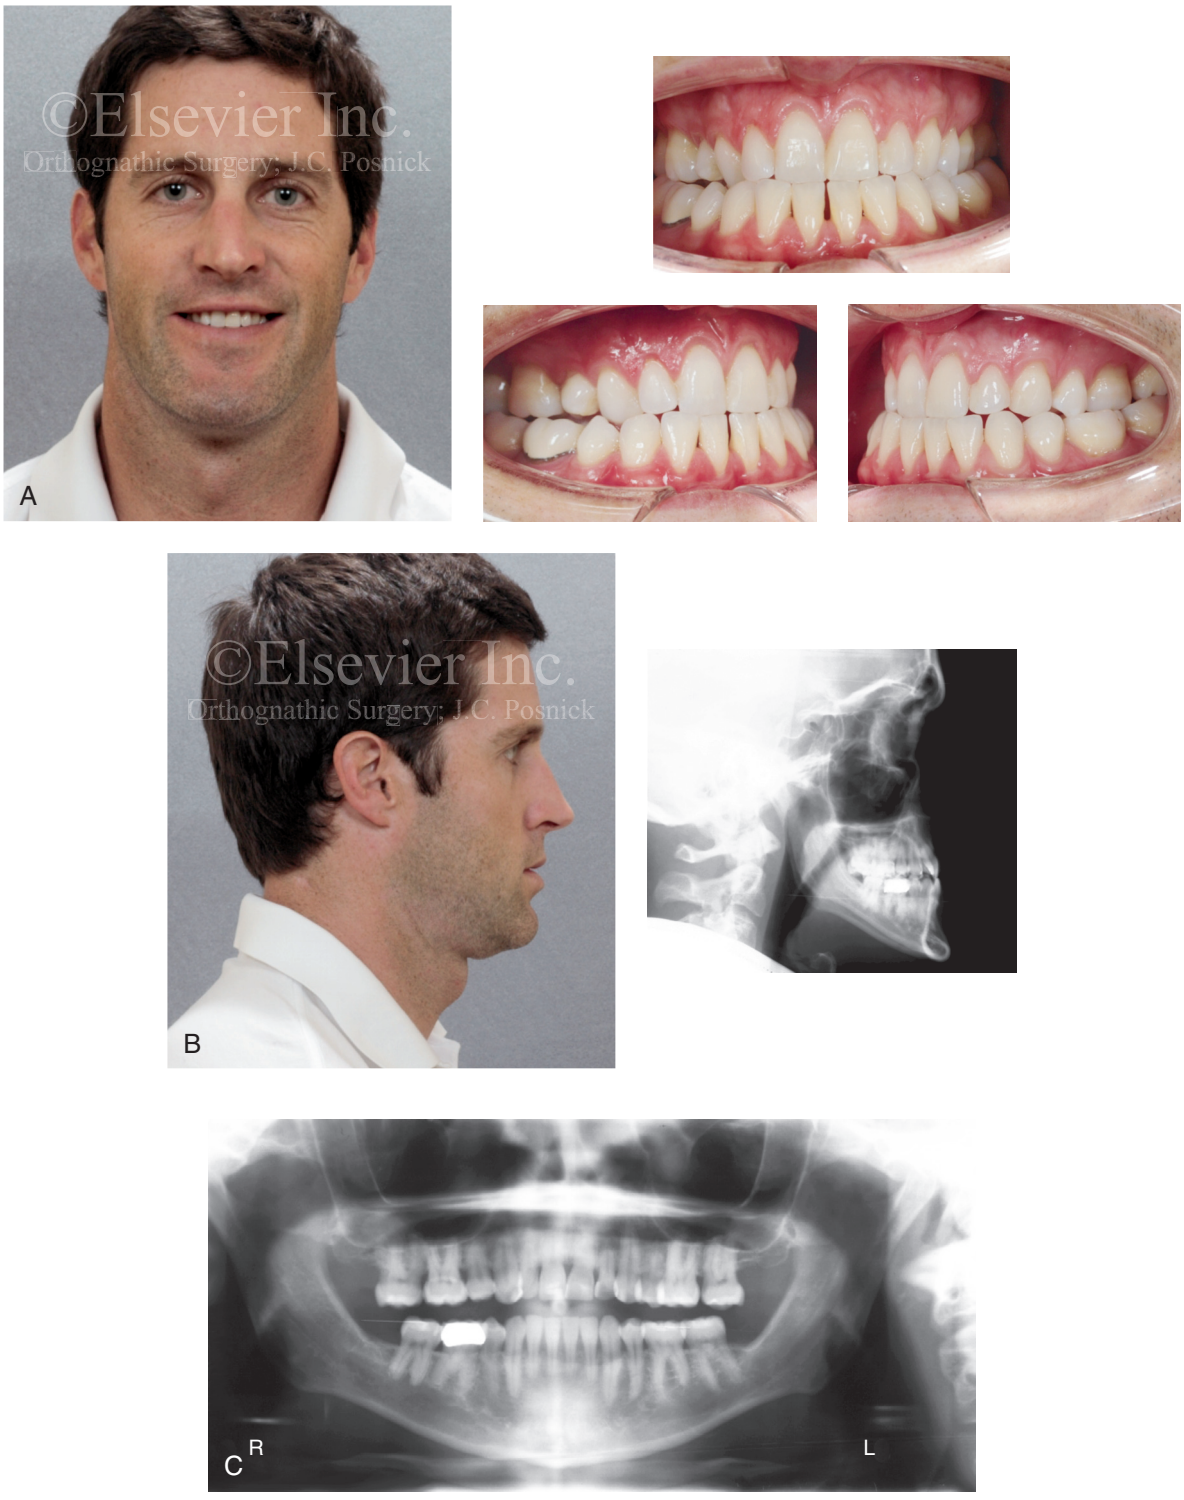
• **Figure 6-18** A woman in her mid 30s was referred by her orthodontist for surgical evaluation. She had a lifelong history of obstructed nasal breathing and a long face growth pattern. Throughout her mid childhood and teenage years, she had undergone attempted growth modification followed by orthodontic camouflage, which included four bicuspid extractions with an attempt to neutralize the occlusion. There is periodontal deterioration and dental relapse with residual malocclusion. The patient agreed to a comprehensive surgical and dental rehabilitative approach. Periodontal treatment was followed by orthodontic (dental) decompensation. Her surgery included maxillary Le Fort I osteotomy in segments (horizontal advancement, vertical shortening, counterclockwise rotation, arch expansion, and curve of Spee correction); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical reduction and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal recontouring (see Fig. 25-8). **A,** Frontal facial and occlusal views before retreatment. **B,** Profile view and lateral cephalometric radiograph before retreatment.

• **Figure 6-19** A woman in her late 40s with a long face growth pattern suffered deterioration of the dentition. The periodontal risk factors included inadequate attached gingiva, dental root crowding within limited alveolar bone support, nasal airway obstruction with forced mouth breathing, and lip incompetence that caused drying of the exposed gingiva. An attended polysomnogram confirmed obstructive sleep apnea. Unfavorable soft-tissue envelope distortions and premature facial aging were also discussed. She agreed to a comprehensive surgical and dental rehabilitative approach. Periodontal treatment was followed by restorative temporization and orthodontic alignment, including the extraction of the four first bicuspids. This was followed by surgery that included maxillary Le Fort I osteotomy in segments (vertical shortening, horizontal advancement, transverse widening, and limited clockwise rotation); bilateral sagittal split ramus osteotomies (horizontal advancement and limited counterclockwise rotation); osseous genioplasty (vertical shortening and horizontal advancement); an anterior approach to the soft tissues of the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication); and septoplasty, inferior turbinate reduction, and nasal floor recontouring (see Fig. 25-3). **A,** Frontal facial and occlusal views before treatment. **B,** Profile view and lateral cephalometric radiograph before treatment.

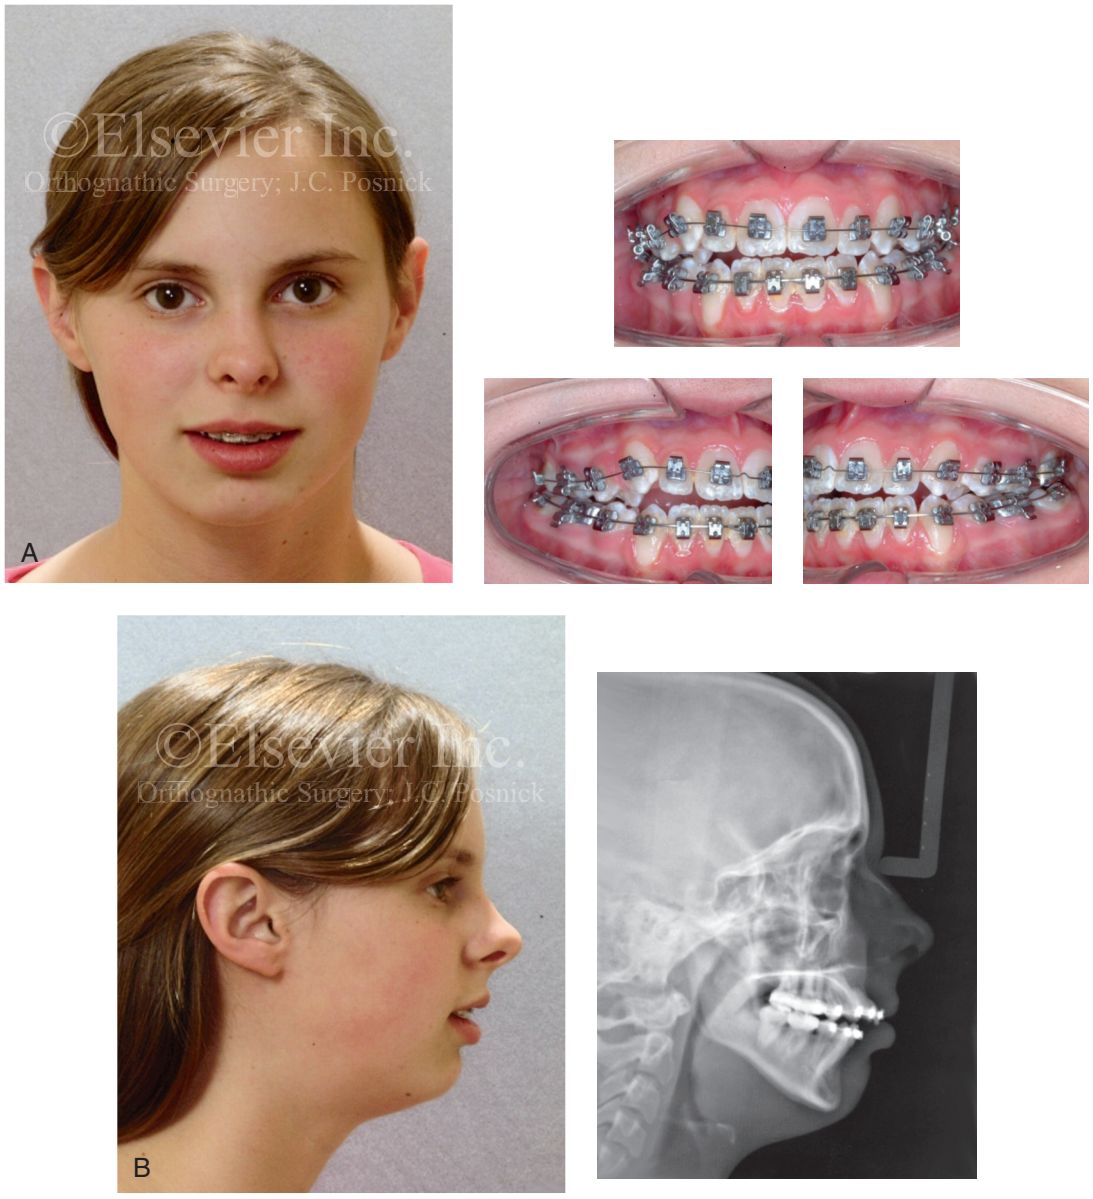
• **Figure 6-20** A 31-year-old man arrived for surgical evaluation. Since the mixed dentition, he was known to have a jaw deformity that was characterized as a maxillary deficiency with relative mandibular excess growth pattern. This results in an Angle Class III, negative overjet, anterior open bite, constricted arch-width malocclusion. The patient is congenitally missing the mandibular first premolars, and he has retained primaries. This surgeon had originally seen him 10 years earlier, when he was 21 years old. An orthodontic and surgical approach was recommended at that time. The patient then declined treatment, but, during the next 10 years, there was further labial bone loss and gingival recession of the mandibular anterior and maxillary posterior dentition. A comprehensive periodontal, orthodontic, and surgical approach was now recommended. The patient had generalized recession, localized minimal attached gingiva, and significant root exposure of teeth nos. 3, 4, 5, 12, 13, and 14. Subepithelial connective tissue grafting was recommended. This is to be followed by orthodontic decompensation and jaw surgery. The procedures are to include Le Fort I osteotomy in three segments (correction of the curve of Spee and the arch width) and bilateral sagittal split ramus osteotomies. **A,** Frontal view with smile and occlusal views at age 21. **B,** Frontal view with smile and occlusal views at age 31. **C,** Profile facial view and maxillofacial i-CAT image that indicate limited alveolar bone covering the roots of the teeth.

• **Figure 6-21** A 32-year-old man arrived for the evaluation of a longstanding jaw deformity with malocclusion, chronic obstructive nasal breathing, and periodontal issues. Since his early childhood years, he was known to have a maxillary deficiency with a relative mandibular excess growth pattern. The family elected a camouflage orthodontic approach in an attempt to neutralize the occlusion when the patient was 9 to 13 years old. He is a forced mouth breather with increased nasal airway resistance as a result of septal deviation and turbinate hypertrophy. His general dentist confirmed labial bone loss and gingival recession of the mandibular anterior and maxillary posterior dentition. He was referred to this surgeon, and a comprehensive orthognathic and dental approach was approved. Consultation with a periodontist, an orthodontist, and an ear, nose, and throat specialist was carried out. The patient was confirmed to have deviation of the septum and enlarged inferior turbinates. An attended polysomnogram is pending. The need for gingival grafting to attain improved root coverage and to generate a wider band of attachment was recommended for teeth nos. 3, 11, 14, 19, 20, 23 through 26, and 29 and 30. This will be followed by the orthodontic removal of dental compensation, including the extraction of a mandibular incisor to address the severe bone loss and gingival recession. Orthognathic and intranasal procedures to improve long-term dental health, to enhance facial aesthetics, and to open the upper airway will follow. **A,** Frontal facial and occlusal views before treatment. **B,** Panorex radiograph with treatment in progress.

• **Figure 6-22** A 30-year-old man arrived for the evaluation of a longstanding jaw deformity with malocclusion, chronic obstructive nasal breathing, and awareness of periodontal issues. Since his early childhood years, he was known to have a jaw deformity with malocclusion that included an anterior open bite. When he was between 8 and 12 years old, he underwent orthodontic camouflage treatment in an attempt to close the open bite, including full bracketing and the use of heavy anterior elastics. By the time he graduated from high school, he was conscious of a significant recurrent anterior open bite with dental crowding. Through his college years, he was aware of gingival recession on the labial aspect of many of the anterior teeth; this was apparent on the maxilla more so than on the mandible. He was sent by his general dentist for an orthodontic evaluation and then to this surgeon for an opinion. He was referred for periodontal evaluation to confirm significant labial bone loss of the anterior dentition (on the maxilla more than the mandible) with gingival recession. A comprehensive approach was recommended, including gingival grafting and four bicuspid extractions with orthodontic retraction of the anterior dentition into solid alveolar bone. This would be followed by jaw reconstruction, finishing orthodontics, and periodontal surveillance. **A,** Frontal facial and occlusal views before retreatment. **B,** Profile facial view and lateral cephalometric radiograph before retreatment. **C,** Panorex radiograph before retreatment.



• **Figure 6-23** A 34-year-old man arrived for the evaluation of a longstanding jaw deformity with malocclusion, chronic obstructive nasal breathing, and periodontal issues. Since his early childhood years, he was known to have a maxillary deficiency with relative mandibular excess growth pattern. The family elected a camouflage orthodontic approach that included four bicuspid extractions and the introduction of dental compensation in an attempt to neutralize the occlusion when the patient was 10 to 15 years old. He is a forced mouth breather as a result of the increased nasal airway resistance. He underwent septoplasty when he was 20 years old, but this did not result in significant improvement. His general dentist confirmed labial bone loss and gingival recession of the mandibular anterior and maxillary posterior dentition. He was referred to this surgeon, and a comprehensive orthognathic and dental approach was recommended. Consultation with the periodontist, the orthodontist, and the ear, nose, and throat specialist was carried out. The patient was confirmed to have residual deviation of the septum and enlarged inferior turbinates, which explained the continued difficulty that he had breathing through his nose. A degree of root resorption of the anterior dentition was likely the result of previous orthodontic mechanics. The need for gingival grafting to attain as much root coverage as possible and to generate a wider band of attachment was recommended for teeth nos. 3, 11, 14, 19, 20, 23 through 26, and 29 and 30. This will be followed by the orthodontic removal of dental compensation and then orthognathic and intranasal procedures to improve the patient's long-term dental health, to enhance his facial aesthetics, and to open his upper airway. **A,** Frontal facial and occlusal views before treatment. **B,** Profile facial view and lateral cephalometric radiograph before treatment. **C,** Panorex radiograph with treatment in progress.



• **Figure 6-24** A 16-year-old girl with a primary mandibular deficiency growth pattern. She had undergone several years of growth modification followed by orthodontic mechanics that included four bicuspid extractions in an attempt to neutralize the occlusion. The patient was left with mandibular deficiency and malocclusion that included significant overjet, anterior open bite, and proclination of the maxillary incisors. Labial bone loss with gingival recession that affected the lower anterior dentition is evident. The patient was referred to this surgeon for a comprehensive orthodontic and surgical approach (see Fig. 19-11). **A,** Frontal and occlusal views in repose at the time of referral. **B,** Profile and lateral cephalometric radiograph views at the time of referral.

• **Figure 6-25** A man in his early 20s with a primary mandibular deficiency growth pattern. He underwent many years of growth modification followed by orthodontic camouflage maneuvers that included four bicuspid extractions in an attempt to neutralize the occlusion. Deterioration of the periodontium with labial bone loss and gingival recession along the mandibular anterior dentition are evident. **A,** Frontal facial and occlusal views before retreatment. **B,** Profile view and lateral cephalometric radiograph before retreatment.

• **Figure 6-26** A woman in her early 50s was referred by a prosthodontist for surgical evaluation. There had been a gradual deterioration of the dentition, which was at least partially a result of the longstanding developmental Class II excess overjet deep-bite skeletal pattern. A head and neck evaluation confirmed a retrusive mandible, which also resulted in retroglossal airway obstruction. In addition, a desire for improved profile aesthetics was discussed. A comprehensive approach to dental rehabilitation, improvement of the upper airway, and facial rejuvenation and reconstruction was recommended. Coordinated endodontic, orthodontic, periodontic, prosthodontic, and surgical care was required. Periodontal treatment, extractions, dental implant placement, restorative temporization, and orthodontic alignment were carried out. These treatments were followed by surgery that included bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical lengthening with interpositional grafting); and an anterior approach to the soft tissues of the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication). These procedure were followed by crown lengthening and then by final dental restorations (see Fig. 25-2). **A,** Frontal facial and occlusal views before treatment. **B,** Profile facial view and lateral cephalometric radiograph during treatment. **C,** Panorex radiograph before treatment.

• **Figure 6-27** A 50-year-old woman was referred by her general dentist to an orthodontist and then for surgical evaluation. There was a mandibular deficiency and a constricted upper jaw growth pattern. This resulted in a Class II deep-bite excess overjet malocclusion. Over the years, there was destruction to the dentition and periodontal apparatus with generalized bone loss and gingival recession. The patient was now under the care of a restorative dentist and a periodontist. To resolve the malocclusion, maxillary expansion and mandibular advancement in combination with orthodontics were recommended. At referral to this surgeon, a history documented heavy snoring, restless sleeping, and daytime somnolence. An attended polysomnogram confirmed a respiratory disturbance index of 42.7 events per hour. There was intranasal obstruction caused by septal deviation and inferior turbinate enlargement, a retropositioned palate caused by maxillary retrusion, and a retropositioned tongue as a result of mandibular retrusion. The soft palate and the tongue were of normal size and function. There were minimum tonsil and adenoid structures. Continuous positive airway pressure was tried but not well tolerated. Surgery was agreed to in combination with orthodontics to improve the malocclusion and to open the airway. The procedures carried out included a maxillary Le Fort I osteotomy (horizontal advancement, vertical lengthening, and arch form correction); bilateral sagittal split osteotomies of the mandible (horizontal advancement); osseous genioplasty (horizontal advancement); septoplasty and inferior turbinate reduction; and an anterior approach to the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication). Subjectively, there was good relief of snoring and restless sleeping as well as the resolution of daytime fatigue. Six months after surgery, an attended polysomnogram confirmed the resolution of the obstructive sleep apnea with a respiratory disturbance index of 1.9 events per hour and minimum desaturation (see Fig. 26-8). **A,** Frontal facial and occlusal views before treatment. **B,** Profile facial view and lateral cephalometric radiograph before treatment.

• **Figure 6-28** A 70-year-old woman arrived for surgical evaluation. She desired a stronger profile, less "loose" neck skin, and an improved smile. She initially requested a face lift and a chin implant. She was found to have a retrusive mandible and dental deterioration that was made worse by dental crowding and a deep-bite negative overjet malocclusion. She underwent orthodontics that included four bicuspid extractions and then surgery that included sagittal split ramus osteotomies (horizontal advancement) and osseous genioplasty (horizontal advancement) (see Fig. 25-10). **A,** Frontal views with smile before and after treatment. **B,** Oblique facial views before and after treatment.

Prior to orthodontics

After treatment including four bicuspid extractions

After treatment

• **Figure 6-28, cont'd C,** Occlusal views before treatment, with orthodontics in progress (including four bicuspid extractions), and after treatment.

• **Figure 6-29** Frontal facial and occlusal views of a 16-year-old boy who had sustained a fracture of the right condyle of the mandible early during his childhood and who presented with the resulting facial asymmetry. He previously underwent several years of orthodontics to neutralize the occlusion. There was loss of labial bone along the anterior mandibular teeth. After surgical evaluation, the patient agreed to a comprehensive orthodontic and orthognathic approach. The procedures included a Le Fort I osteotomy, a left sagittal split ramus osteotomy, the reconstruction of the right condyle with a costochondral graft, and an osseous genioplasty (see Fig. 35-8). Note the recession along the labial aspects of the mandibular incisors before surgery. Gingival grafting is indicated. *From Posnick JC: Management of facial fractures in children and adolescents.* Ann Plast Surg *33:453, 1994.*

Effects of Inadequate Attached Gingiva

There are significant intrinsic biologic variations between humans with respect to the morphologic characteristics of the gingiva; this is known as the *gingival biotype.*[52,73,138] The evaluation of the individual's gingival biotype is important to orthodontic treatment planning, because thick and thin gingival biotypes are frequently associated with varied osseous patterns. These two tissue types are likely to respond very differently to similar orthodontic forces by demonstrating different patterns of osseous remodeling. With an understanding of the nature of the individual's biologic risk factors (e.g., gingiva, alveolar bone, breathing pattern, degree of malocclusion), appropriate periodontal, orthodontic, and surgical preventative procedures and precautionary measures may be instituted to provide a more favorable tissue environment to minimize alveolar bone loss and gingival recession. Historically, Ochsenbein and Maynard discussed the importance of thick versus thin gingiva with regard to restorative treatment planning.[150] In addition, in a group of patients reviewed by Olsson and colleagues, a thick periodontal biotype (85% of population) was found to be more prevalent than a thin periodontal biotype (15% of population).[152] Thick gingival tissue is dense in appearance, with a fairly large zone (length) of attachment. The gingival topography is relatively flat, which is suggestive of a full underlying bony architecture. Thin gingival tissue tends to be delicate and almost translucent in appearance. The tissue is friable, with a minimal zone of attachment; this is suggestive of minimal bone over the labial roots of the teeth. The diametrically opposite thin and thick gingival biotypes will respond differently when subjected to inflammation, mechanical trauma, orthodontic forces, or surgical insults. Results from at least some clinical studies indicate that, as long as a tooth is being orthodontically moved with light forces and within or into (and not out of) the alveolar process, then the risk of harmful side effects on the marginal (gingival) soft tissues is minimal.[212-215] In current clinical practice, pretreatment gingival augmentation (i.e., free gingival grafts, lateral pedicled flaps, and autogenous and allogenic connective tissue grafts) to improve the presenting thin keratinized gingiva—in combination with light orthodontic force—generally achieves objectives and limits recession and alveolar bone loss.

Effects of Inadequate Alveolar Bone (Alveolar Bone/Dental Root Ratio)

There will be inherent biologic variations among individuals with regard to the extent of alveolar housing as compared with the cumulative dental root volume of the compliment of teeth within each arch; this is known as the *alveolar bone/dental root ratio.*[184,199] When the roots are crowded into

limited available alveolar housing, the periodontal tissues are less able to withstand the routine inflammatory processes and the mechanical demands that they experience. In turn, the periodontium may recede (i.e., experience bone loss and gingival recession). To prevent this, either the space within the arch must be increased (e.g., rapid palatal expansion, surgically assisted rapid palatal expansion, segmental osteotomies) or extractions must be carried out as part of orthodontic treatment to limit the risk of periodontal deterioration.[50,58,101,103,114,119,147,168,217] Orthodontic relief of dental crowding in the upper jaw by simply expanding the crown arch form in the presence of an inadequate alveolar arch form may align the dental crowns, but it will predictably result in cortical plate thinning, with the potential for dehiscence, fenestrations, loss of alveolar ridge height, and gingival recession (Fig. 6-8). Under these circumstances, successful dental uncrowding without extractions requires the initial expansion of the maxillary (skeletal) arch (e.g., rapid palatal expansion, surgically assisted rapid palatal expansion, segmental osteotomy).[108] By following these principles, the achievement of improved arch form with the preservation of periodontal health should be possible.[147]

Effects of Nasal Obstruction and Mouth Breathing With Resulting Vertical Maxillary Excess, Lip Incompetence, and Inadequate Incisor/Gingiva Coverage

There is considerable variation among humans with respect to *biologic respiratory patterns* (i.e., mouth breathing versus nasal breathing). In the presence of significant nasal obstruction, a forced mouth-breathing pattern will occur and have the potential to cause detrimental effects on the periodontium.[7,102,113,206] The existence of these two very different airway biotypes (i.e., nasal breathing and mouth breathing) and the secondary effects that may result should be recognized. Mouth breathing is an important etiologic factor for chronic gingivitis and chronic marginal periodontitis as well as for the formation of dental plaque and calculus. The presence of marginal gingivitis in individuals with mouth breathing was described in the literature by **Coleyer** in 1920. **Warwick and Hastings** (1933) also claimed that the surfaces of teeth and gingiva that were constantly exposed to air (i.e., in individuals who breathe habitually through the mouth) did not have the benefit of normal irrigation with saliva; these surfaces also did not benefit from the normal friction effects that result from the vestibular mucosa moving against the teeth and gingiva that would normally occur during lip closure.

In a normal human physiologic state, nasal breathing is a primary source of air intake; it is essential for the supply of properly cleansed, moist, warm air to the lungs. The mouth is considered the secondary emergency source of air for breathing. Individuals who primarily breathe through the mouth also tend to have an excessively open lip posture (i.e., >4 mm), and they often have reduced lip coverage of the incisors and the gingiva. Epidemiologic studies suggest an increased susceptibility to gingival inflammation among mouth breathers. The exact mechanism of these effects is not entirely known, but it is thought that the gingiva of the anterior teeth in particular is prone to drying out as a result of a lack of saliva. This scenario will also lead to an absence of the natural protective action of the saliva and the lips.

Gulati and colleagues undertook a study to assess the effects of mouth breathing, lip seal, and upper lip coverage on the gingival health of children.[98] School-aged children between the ages of 10 and 14 years (n = 240) were selected for the study. After clinical examination, they were divided into two major groups: mouth breathers and normal breathers. These two groups were further subdivided into six subgroups on the basis of lip-seal ability and upper incisor lip coverage. The results of the study indicate a gingival index that is higher in mouth breathers with lip incompetence than in normal breathers. Increased lip separation and decreased upper lip coverage (i.e., excess exposure of the maxillary incisors) were also associated with higher plaque and gingival indices.

Alexander completed clinical research with the intent of understanding habitual mouth breathing and its effect on gingival health.[7-9] The study included 200 patients with a mean age of 30 years who were attending a clinic for routine dental treatment. Each of the subjects underwent systematic examinations to evaluate the presence of gingival inflammation, supragingival and subgingival calculus, and bacterial plaque. Each detailed examination was carried out under standardized conditions. Individuals were questioned carefully regarding the manner in which they usually breathe (i.e., mouth breathing versus nasal breathing). Mean gingival inflammation scores, calculus surface indices, and bacterial indices (with erythrosine disclosing solution) were calculated for each of their individual teeth. The study results confirm that habitual mouth breathing is highly associated with an increase in gingival inflammation and the prevalence of supragingival and subgingival calculus (see Figs. 6-15 through 6-22).

Fukuda and colleagues completed a study to evaluate the influence of mouth breathing on the periodontal tissues.[76] Ten patients with chronic marginal periodontitis who were found to be habitual mouth breathers were included in the study, and they were evaluated for 30 days. During the experimental time frame, the study patients underwent taping of the lips to accomplish lip seal and to limit the mouth breathing option while sleeping. Oral examinations were completed and biopsy specimens of the gingiva were taken before and after nighttime lip tapings. The study indicates that, with satisfactory lip seal (i.e., lip taping), forced primary nasal breathing was achieved in these individuals while they were sleeping. This resulted in the following:

1. Halitosis and the uncomfortable feeling in the mouth upon awakening were decreased significantly.
2. The depth of the periodontal pockets and the labiolingual width of the gingiva were both decreased. The improvement was primarily seen on the labial side of the maxillary dentition.

3. The vacuolar degeneration of the epithelial cells was decreased as confirmed by histopathologic examination. However, inflammation of the connective tissue did not show improvement during the 30-day treatment time.

Effects of Malocclusion on Periodontal Health

Bollen completed a systematic review of the literature to answer the question, "Does a malocclusion affect periodontal health?"[35] An electronic search included all publications from 1960 through 2006. A total of 25 studies that evaluated the association between a malocclusion and periodontal health were of sufficient quality for inclusion in the review.* Only 5 of these 25 studies adjusted for factors such as age, socioeconomic status, and oral hygiene. The total number of subjects included in the 25 studies was 35,300, and they had a mean age of 22 years (range, 3 to 60 years). Pertinent results of the review included the following:

1. Nineteen of the 25 studies found greater periodontal disease among subjects with greater malocclusion.
2. Six studies considered the interaction between malocclusion and "periodontopathies." These studies found significantly greater periodontal problems among subjects with malocclusions as compared with subjects without malocclusions ($P < .0001$).
3. Two studies looked at the interaction between malocclusion and gingivitis. These studies found greater levels of gingivitis among subjects with malocclusions as compared with subjects without malocclusions ($P < .0001$).

The conclusions drawn by Bollen suggest that there is often a correlation between the presence of malocclusion and periodontal disease. However, the extent of this correlation, which is found in large population studies, should not be interpreted as demonstrating a clear cause and effect for any given individual.[4,5]

Potential Detrimental Effects of Orthodontic "Camouflage" Maneuvers on the Periodontium

Orthodontic camouflage maneuvers and dental restorative procedures carried out in an attempt to neutralize the malocclusion may be additive to the individual's biologic risk factors with regard to his or her potential for progressive deterioration of the periodontium (see Figs. 6-16 through 6-25).

*References 23, 28, 32, 33, 44-46, 53, 55, 64, 65, 72, 77, 79-86, 95, 96, 105, 109, 110, 112, 118, 120, 123, 137, 143, 145, 149, 163, 187, 188-190, 196, 201, 208

Long Face Growth Pattern

In the individual with a *long face growth pattern,* orthodontic camouflage maneuvers may attempt to correct maxillary arch–width deficiency via the buccal tipping of the posterior teeth (see Figs. 6-15 through Fig 6-19). If more than a few millimeters are required, this may result in the remodeling of the alveolar process with dehiscence and fenestration of the buccal cortex, followed by gingival recession.[27,205,207,209]

Orthodontic mechanics that are carried out in an attempt to manage the skeletal component of an anterior open bite often "extrude" the incisors. A biologic consequence may be the remodeling of the alveolar process with dehiscence and fenestration of the mandibular labial cortex, followed by gingival recession. Maxillary incisor root resorption may also occur.

Maxillary Deficiency With Relative Mandibular Excess Growth Pattern

With a *maxillary deficient and relative mandibular excess growth pattern,* orthodontic camouflage maneuvers often attempt to correct upper arch–width deficiency via the buccal tipping of the posterior teeth (see Figs. 6-14 and 6-20 through 6-23). If more than a few millimeters are required, this may result in the remodeling of the alveolar process with dehiscence and fenestration of the buccal cortex, followed by gingival recession.[27,205,207,209]

Orthodontic mechanics that are carried out to manage the skeletal component of the negative overjet often result in the proclination of the maxillary incisors and retroclined mandibular anterior teeth. This approach may result in the remodeling of the alveolar process with dehiscence and fenestration of the mandibular labial cortex, followed by gingival recession. The remodeling of the alveolar process with a loss of maxillary labial cortex may also be seen.[185,194,210]

Primary Mandibular Deficiency Growth Pattern

In the individual who presents with a *primary mandibular deficiency growth pattern,* orthodontic camouflage maneuvers often attempt to uncrowd the mandibular arch by "flaring" the anterior dentition and to then decrease the overjet by proclining the incisors even further (see Figs. 6-24 through Fig. 6-28). This may result in the remodeling of the alveolar process with dehiscence and fenestrations of the labial cortex, followed by gingival recession.[10-15,18,26,64,65,72,178,195,211]

Another common error occurs when mandibular advancement surgery is planned to correct the excess overjet. Often an inter–arch-width discrepancy will be unmasked (i.e., in approximately 30% of cases). It is not uncommon for clinicians to then avoid maxillary surgery through the process of orthodontic buccal tipping the maxillary posterior teeth to relieve the crossbites. If more than a few

millimeters are required, this may result in remodeling of the alveolar process with dehiscence and fenestration of the buccal cortex followed by gingival recession[180] (see Figs. 6-24 through 6-28).

Establishing a Healthy Periodontium and Periodontal Therapeutics

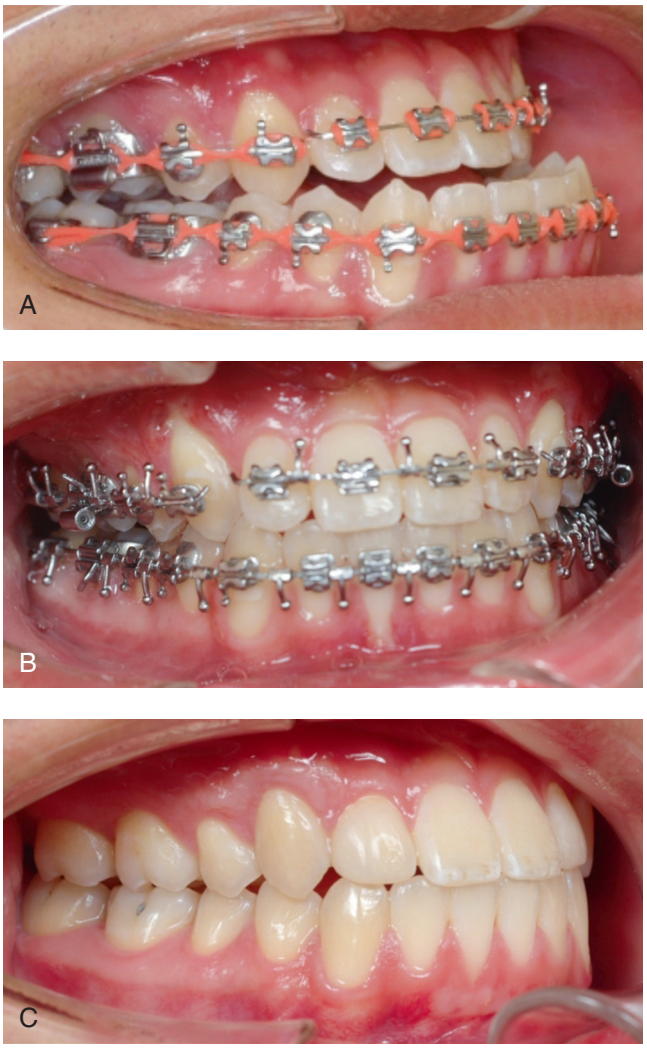
Before the initiation of orthodontic treatment, the clinician should assess for adequate attached gingiva (i.e., the need for grafting); adequate alveolar bone (i.e., the need for extractions or alveolar expansion); caries and plaque control (i.e., the need for hygiene instruction, deep scaling, and root planing); the adequacy of dental restorations (i.e., the need for restorative dentistry); the adequacy of nasal breathing (i.e., the need to open the airway through intranasal surgery); and the adequacy of lip closure (i.e., the need for jaw surgery).[16,17] When a jaw discrepancy is present (with or without combined nasal obstruction and lip incompetence), the orthodontic objectives should be modified to include the coordination of surgical treatment to achieve the desired end results.

A primary focus of *periodontal therapeutics* is to reduce inflammation by creating an environment that can be maintained as free of plaque as possible.[2,3,22,87,136,159,164,166] After this is accomplished, the individual can be trained to perform the task of deplaquing the dentition and developing an effective habit of doing so at least once every 24 hours.[179,186] Plaque-retaining traps will limit the individual's ability to effectively deplaque the dentition.[91] These traps include calculus, crowded teeth, malaligned teeth, restorative overhangs, overcontoured teeth, root anomalies, subgingival caries, and pocketing.[97] Consultation with a periodontist is useful, because his or her skills include the ability to diagnose and remove plaque traps and also to effectively educate the affected individual with regard to how best to maintain clean teeth.[130] Limiting plaque traps may also require orthodontic procedures to reposition dental crowns into more healthy relationships and to place roots more fully within the alveolar bone. This may be combined with procedures to surgically align the jaws (e.g., orthognathic correction) and to open the nasal airway (e.g., septoplasty, inferior turbinate reduction).[48,51,71,74,75,78,88,90,94,140,158,162,167,168] Misguided orthodontic tooth movement carried out in isolation or in combination with surgery can result in injuries that includes the loss of alveolar crestal height, the dehiscence of or fenestrations through the labial and lingual plates, gingival recession, root resorption, tooth mobility, and inadequate occlusion (see Figs. 6-29 and 6-30).[42,60,61,127,128,146,148,153]

Adult Orthodontic Treatment

Throughout the more advanced countries in the world, there has been a continuous increase in the number of adults who are seeking orthodontic treatment. There is a growing desire to maintain the dentition throughout life and an awareness of the importance of a comprehensive dental rehabilitative approach to do so. The orthodontic movement of teeth and the level of orthodontic force applied have potential effects on the surrounding alveolar bone, the PDLs, and the gingival attachments.

With aging, there tends to be progressive reduction of the periodontium, an increase in the root–tooth ratio, and a decrease in the resistance to spontaneous tooth migration. For these reasons, a reduced baseline periodontium may be



• **Figure 6-30** A 17-year-old high school student was referred by his orthodontist for surgical evaluation. The Class III negative overjet anterior open-bite malocclusion required retreatment with orthodontics, including maxillary bicuspid extractions and jaw surgery. With a lifelong history of nasal obstruction and consistent physical findings, intranasal procedures were also required. With orthodontic (dental) decompensation complete, the patient's surgery included a maxillary Le Fort I osteotomy in segments (arch expansion, horizontal advancement, and vertical lengthening); sagittal split ramus osteotomies (limited corrections); osseous genioplasty (vertical reduction and minimal horizontal advancement); and septoplasty and inferior turbinate reduction. Occlusal views **A,** before retreatment, **B,** with orthodontics in progress, and **C,** after the completion of treatment. The patient required and underwent gingival grafting on the labial aspect of the right maxillary canine after the removal of the orthodontic appliances.

present more frequently in adults than in adolescents. These periodontal findings must be taken into consideration before the initiation of an orthodontic program. With age, there may also be an increase in bone porosity (i.e., decreased density). The initial reaction of the PDL and the alveolar bone to orthodontic loading in the adult may be delayed. However, after tooth displacement gets under way, treatment can be carried out in the same way in the adult as it is in a teenager or a young adult. There is no known age limit to the orthodontic movement of teeth (see Fig. 6-28). By contrast, it is known that the precondition of the periodontium should be one of health and anatomic adequacy to mitigate the risks to the periodontium during orthodontic therapy. The presenting periodontium—whether normal or diminished—should be healthy when tooth movement is initiated.

Conclusions

The periodontium includes the investing and supporting tissues of the teeth, and it consists of the attachment apparatus and the dentogingival unit. The degeneration of the periodontium is likely to accelerate in the presence of specific intrinsic biologic factors (i.e., the individual's biotype), which may include a baseline jaw discrepancy with malocclusion; the crowding of the dental roots within limited alveolar bone; a forced mouth-breathing pattern; and an inadequate amount of attached gingiva at the clinical crown interface of the teeth. Active infection or inflammation of the periodontium, non-biologic restorations at the dental–gingival interface, para-occlusal habits, local toxins, and poor oral hygiene also negatively affect the periodontium.

Before the initiation of orthodontic treatment, the clinician should assess for the patient's specific risk factors for periodontal disease and address them. When a jaw discrepancy is present, the orthodontic objectives should be modified to include the coordination of surgical treatment to best preserve the periodontium and to achieve the desired end result.

Psychosocial Considerations in the Evaluation and Treatment of Dentofacial Deformities

JEFFREY C. POSNICK, DMD, MD

- Psychosocial Aspects to Consider Before Surgery
- Body Dysmorphic Disorder
- Psychological Functioning in the Individual With a Facial Deformity
- Patient and Family Decision for or Against the Correction of a Dentofacial Deformity
- Patient and Family Education Regarding Convalescence After Orthognathic Surgery
- Patient-Centered Assessment of Surgical and Orthodontic Outcomes
- Controversies Surrounding "Successful" Orthognathic Outcomes
- Conclusions

Individuals who present with dentofacial deformities do not comprise a monolithic group. They may arrive for evaluation during childhood, adolescence, early adulthood, or it may be later in life. The etiology of the jaw deformity may be congenital, developmental, or posttraumatic, or it may have occurred after tumor resection that required radiation therapy. A combination of orthodontic treatment and orthognathic surgery—often in conjunction with additional dental rehabilitation—may be required to correct the skeletal deformities, to improve head and neck function (i.e., chewing, breathing, speech, swallowing, lip control), to enhance facial aesthetics, and to restore the dentition.

The initial discussion regarding the need for orthognathic surgery may come as a surprise to the patient and his or her family. This is especially true for the individual whose jaw dysmorphology occurred gradually during facial development, without special attention being drawn to it all of a sudden as would occur from a traumatic event, a birth defect, or after tumor resection.[9,10,37,68,71,80,81,101,103] Although they have typically been aware of the malocclusion and the associated facial characteristics for at least several years, the patient and his or her family generally assume that orthodontics alone or some other minimally invasive approach is all that will be required for treatment.[87] The orthodontist may have already exhausted the patient and his or her family's energy and resources with several years of treatment to "avoid surgery" before finally "giving up." The family may have inaccurate preconceived ideas about the surgery and the patient's expected convalescence. The decision-making role of the parents and the compliance (i.e., the attitude) of the adolescent patient will also be important. Any dysfunctional family interactions involving the mother, the father, the patient, or the patient's siblings, stepparents, or grandparents at this moment of stress (i.e., when a decision is needed) may also come into play. From the adolescent's point of view, social interactions with his or her peers and concerns about the interpretation (by others) of any change in his or her appearance—as well as his or her evolving self-image and identity—will also have an impact on the situation in ways that are ongoing and somewhat unpredictable.

Frequently, the treating clinicians (i.e., the surgeon, the orthodontist, the restorative dentist, and the general physician) judge success or failure according to specific anatomic or numeric benchmarks, such as achieving a Class I occlusion, normative cephalometric radiographic measurements, and successful wound healing. Although patients and their families do consider stable occlusion and a lack of wound healing complications to be important aspects of success, there are likely to be other motives and objectives that cannot be overlooked if patient satisfaction is to be achieved. It is not uncommon for an orthognathic surgical result to be labeled as suboptimal by the surgeon, the orthodontist, or the restorative dentist as a result of an imperfect occlusion, whereas the patient's satisfaction rating will be more

favorable. It is just as likely that the treating clinicians may feel that a successful outcome has been achieved (i.e., satisfactory occlusion and uncomplicated wound healing), whereas the patient may feel that the aesthetic objectives have not been fully met.

Research confirms a correlation between an adolescent's self-reporting of improved appearance ratings and a decrease in social, physical, and psychological problems after successful reconstruction.[58,67,73,78] Patel and Kapp-Simon prospectively studied 70 teenagers who were slated to undergo orthognathic surgery.[69] Before surgery, 78% stated that a functional reason was their primary motivation for undergoing orthognathic surgery. Not surprisingly, before surgery, the adolescents rated their appearance significantly less favorable than their parents did. Two years after surgery, the adolescents reported significantly increased self-confidence, and a majority (58%) felt that they had achieved improvements in their facial appearance as a result of surgery. They stated that improvements in their facial appearance would be a motivating factor for them to undergo similar surgery again. It would appear that, when all is said and done, adolescents—like adults—rate the enhancement of their facial appearance as a high priority when measuring the success or failure of their orthognathic procedures. Experience confirms it is better to openly discuss facial aesthetic aspects before surgery. This encourages the clinician to set realistic objectives, and it forces the patient and the family to confront their outcome expectations in advance.

Both adolescents and adults undergoing orthognathic surgery should be screened to assess emotional baseline functioning as well as psychological readiness for surgery. The pre-surgical mental health screening should clarify any past or current symptoms of depression, anxiety disorders, panic attacks, aggression, drug/alcohol use, eating disorders, school-related problems, family or social (peer) dysfunctional relationships.[4]

Psychosocial Aspects to Consider Before Surgery

Personal Motivation

The individual's personal motivation to seek the correction of a dentofacial deformity is an important factor for clinicians to consider (Figs. 7-1 through 7-5).* In 2000, Rivera and colleagues surveyed 142 patients regarding their reasons for choosing to undergo orthognathic surgery.[86] Seventy-one percent indicated facial aesthetic concerns, 47% stated functional issues, and 28% confirmed temporomandibular disorders as their reasons for seeking treatment. In 2007, Narayanan and colleagues surveyed 50 patients who sought orthognathic surgery and found that, for the majority, facial aesthetics rather than the correction of their occlusions was the primary motivating factor.[59] In 2007, Stirling and colleagues conducted a questionnaire and interview survey of individuals who had undergone orthognathic surgery. The 46 interviewed patients stated that their primary motivations generally included both "improvement of the occlusion and to gain a more normal facial appearance."[97] More recently, Proothi, Drew, and Sachs completed a retrospective survey of 501 individuals who underwent orthognathic surgery to determine why they sought the procedures.[83] The survey group was 43% male and 57% female, and the individuals ranged in age from 12 to 45 years. Seventy-six percent stated that facial appearance was negatively affected by their pretreatment jaw condition, but only 15% claimed that their appearance was their primary motivation for undergoing surgical evaluation. Thirty-six percent stated that their occlusion was the primary motivating force. Interestingly, 33% admitted to having significant speech difficulties, and 15% complained of swallowing problems that resulted from their presenting jaw deformity.

All adolescents more or less struggle with issues related to self-identity, social acceptance, and physical appearance. The added factor of a dentofacial deformity with impaired head and neck function and negative effects on physical appearance—coupled with the need to make a decision for or against surgical correction—may compound these psychological issues. If the individual already has baseline depression, anxiety, poor self-confidence, or other social issues, the presence of a dentofacial deformity with the need for surgical correction is likely to exacerbate these symptoms. The extent to which an exacerbation of baseline symptoms occurs may depend on how much the lack of self-confidence and social problems relate to the dentofacial deformity.

A typical sequence of events is a pre-adolescent individual being referred by his or her general dentist to an orthodontist for the correction of a malocclusion. The orthodontist may have then attempted growth-modification techniques followed by a camouflage approach to "improve" the occlusion for a period of time that ranges from 2 to 8 years before finally "giving up" and suggesting a surgical referral. The adolescent and his or her family may also have pushed for a surgical referral in response to concerns about facial aesthetics and a lack of progress with regard to the full correction of the malocclusion by the orthodontist who initially felt that he or she could solve the problem with orthodontics alone. With today's evidence-based thinking, knowledgeable clinicians should recognize the need for a surgical approach from the outset.

The adolescent and his or her parents' motivation for correction may be clearly stated to the surgeon at the initial introduction, or it may be only indirectly discussed. The patients' and their families' perceptions of the surgical outcomes will be important to achieving a smooth recovery and a favorable outcome. The results—both functional and aesthetic—should be clearly and realistically articulated by the surgeon, openly discussed, and agreed to by all parties before proceeding.

Text continued on p. 218

• **Figure 7-1** A 17-year-old boy who was born with a nonprogressive congenital myopathy was referred by an orthodontist for surgical evaluation. The lack of masticatory muscle strength resulted in a constant open mouth posture. The long face growth pattern is characterized by vertical maxillary excess; a clockwise-rotated retrusive mandible; a vertically long and retrusive chin; and an Angle Class II anterior open-bite malocclusion. The patient underwent a combined orthodontic and surgical approach. Four bicuspid extractions relieved dental crowding. This was followed by surgery that included a maxillary Le Fort I osteotomy (vertical intrusion and horizontal advancement); bilateral sagittal split osteotomies of the mandible (horizontal advancement and counterclockwise rotation); and osseous genioplasty (vertical reduction and horizontal advancement). **A,** Profile views before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

• **Figure 7-2** A 15-year-old girl was referred by her orthodontist for surgical evaluation. She had a long face growth pattern and a Class II anterior open-bite malocclusion. She had been treated for several years with orthodontics alone, and this included four bicuspid extractions. The anterior open bite was essentially closed, with only minor degrees of malocclusion. The history and physical examination confirmed lifelong nasal obstruction, heavy snoring, and the suggestion of sleep apnea. Facial aesthetic concerns of the patient and her family included an awareness of a gummy smile, severe lip strain, a weak profile, and an irregular shape and position of the lips. The family agreed to an orthognathic approach. The procedures performed included a maxillary Le Fort I osteotomy (vertical shortening and horizontal advancement with counterclockwise rotation); bilateral sagittal split osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (horizontal advancement and vertical shortening); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Oblique facial views before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

NOTE: Improved sleep at night resulted in less daytime fatigue and better concentration at school. Positive psychosocial effects were appreciated and easily adjusted to by the patient.

• **Figure 7-3** A 16-year-old girl was referred by her orthodontist for surgical evaluation. She had a long face growth pattern in combination with asymmetrical mandibular deficiency. This resulted in difficulty with speech articulation, swallowing, chewing, and lip closure/posture. Facial aesthetic awareness of a gummy smile, lip incompetence, a weak profile, and lip irregularities was discussed. With orthodontic decompensation complete, orthognathic surgery was carried out. The procedures performed included a maxillary Le Fort I osteotomy in three segments, with first bicuspid extractions (vertical retrusion, arch form correction, and counterclockwise rotation); bilateral sagittal split ramus osteotomies (horizontal advancement, counterclockwise rotation, and asymmetry correction); and septoplasty, inferior turbinate reduction, and nasal floor contouring. **A,** Profile views before and after treatment. **B,** Frontal views with smile before and after treatment.

NOTE: Improvements in function (chewing, speech, swallowing, and lip closure) were immediately appreciated and accepted by the patient. The patient's psychosocial adjustment to the consistent positive comments from her peers required some accommodation. This included adjusting to not being visually recognizing as the same person by many past acquaintances.

• **Figure 7-4** A 14-year-old girl was referred by her orthodontist for surgical evaluation of a dentofacial deformity. She had a long face growth pattern that presented with excessive vertical height and significant horizontal projection and narrowness of the maxilla and the midface. She had limited airflow to the nose, severe lip incompetence, and the impression of a weak chin. Several years of orthodontics have already been carried out, and she agreed to surgical reconstruction. The procedures performed included a maxillary Le Fort I osteotomy in three segments with first bicuspid extractions (vertical intrusion, horizontal setback, and arch correction) as well as septoplasty, inferior turbinate reduction, and nasal recontouring. **A,** Profile views before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

NOTE: Improvements in speech articulation, swallowing, chewing, and lip closure were easily adapted to by the patient. After some time, her self-esteem improved, and she became less shy and withdrawn as compared with her behavior before surgery.

• **Figure 7-5** A 16-year-old congenitally blind girl presented with maxillary and mandibular protrusion and anterior open-bite malocclusion. Although she was unable to visualize the deformity, she felt self-conscious after years of teasing as a result of her facial appearance and her difficulties with chewing, swallowing, and speech articulation. The patient underwent a combined orthodontic and surgical approach. The procedures performed included a maxillary Le Fort I osteotomy (vertical intrusion and horizontal setback) and bilateral sagittal split osteotomies of the mandible (horizontal setback). **A,** Frontal views before and after reconstruction. **B,** Oblique facial views before and after reconstruction.

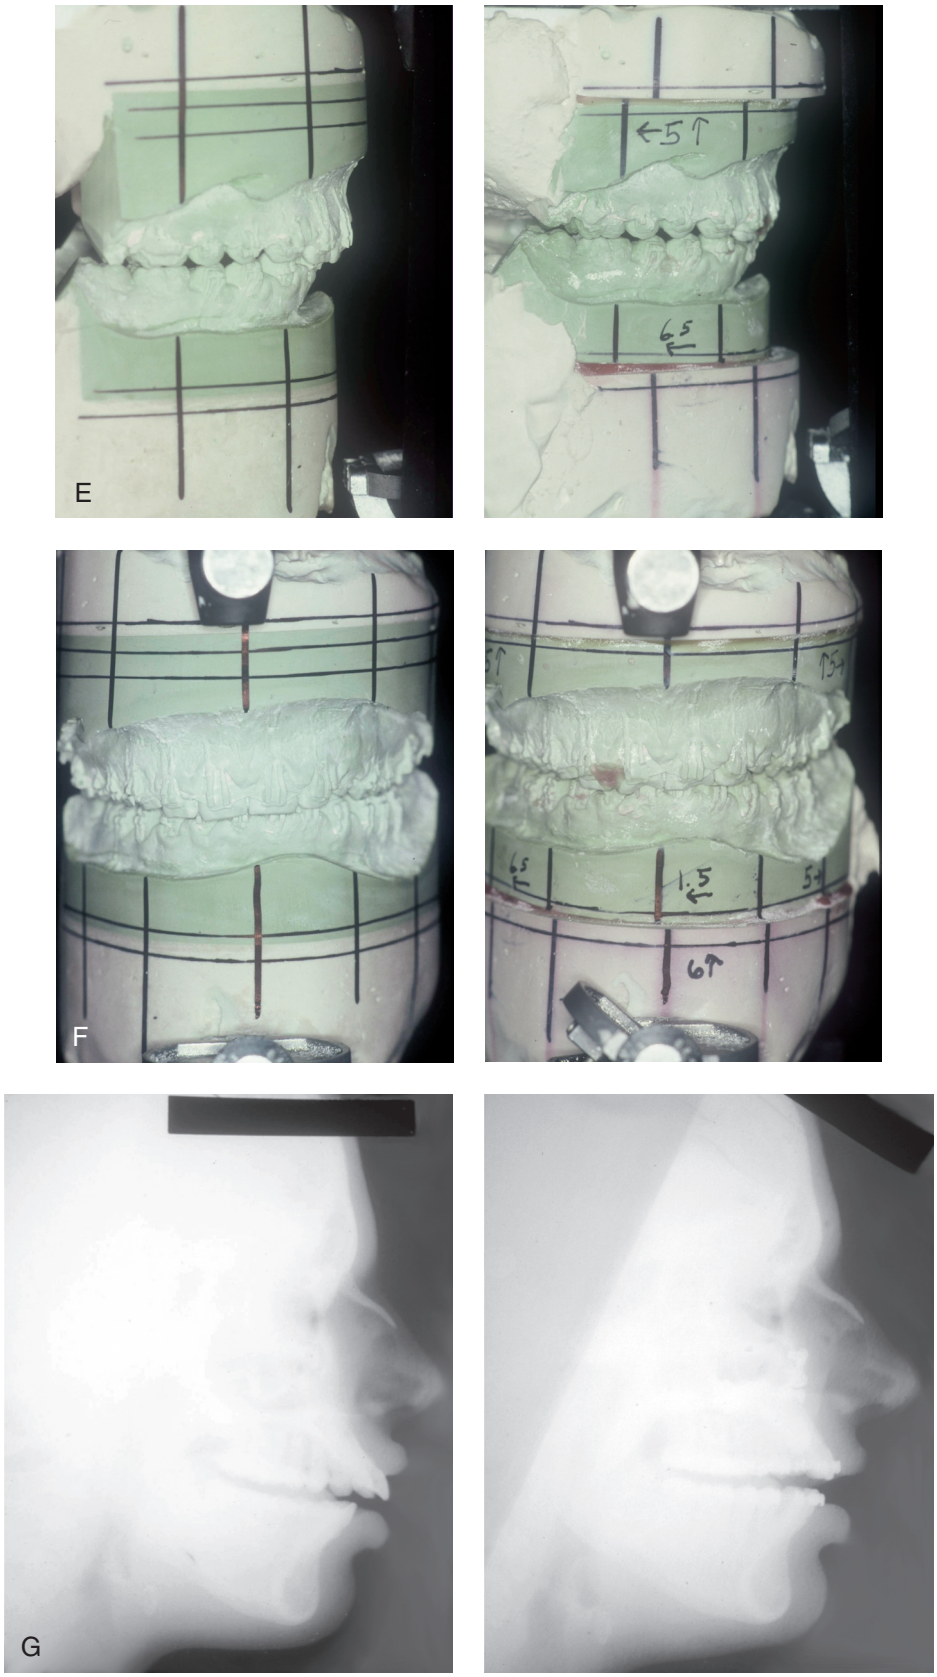
Pre treatment

After treatment

• **Figure 7-5, cont'd C,** Profile views before and after reconstruction. **D,** Occlusal views before and after reconstruction.



• **Figure 7-5, cont'd E** and **F,** Articulated dental casts that indicate analytic model planning. **G,** Lateral cephalometric radiographs before and after treatment.

Baseline Mental Health

Individuals who do not have sufficient preoperative psychological or emotional stability are more likely to experience depression, anxiety, or panic attacks and to demonstrate difficulty complying with treatment demands during the early postoperative phase.[16,17,21,27] They will also have greater difficulty with an outcome that does not meet their preconceived and often incompletely articulated expectations. If so, after surgery, they may become easily frustrated and then angry, and this may involve a loss of confidence in the surgeon. They may break off communication and seek additional opinions to justify their concerns. Some may even resort to litigation should a perceived complication or suboptimal outcome occur. Recognizing and addressing these patient-specific tendencies before surgery is the best way to limit or mitigate problems after surgery.

After an initial screening examination, a more in-depth psychological evaluation may be beneficial.[8,18,24,96] The patient and his or her family's motivation and the patient's readiness for surgery should also be assessed. Unless a sufficient support system is in place, the stress of the necessary convalescence is likely to worsen any premorbid conditions in the patient. An initial screening that results in red flags for potential emotional problems is best followed up with a more focused psychological evaluation. The patient's therapist should give clearance that the individual is considered emotionally stable enough to undergo the proposed treatment. When the treating clinicians (i.e., the surgeon, the orthodontist, and the general physician) have knowledge of the patient's premorbid tendencies, coping strategies can be instituted proactively to minimize postoperative stress. The treating mental health professional should be available to the patient, the family, and the surgical team during hospitalization, after discharge, and throughout the patient's convalescence.

High-Risk Social Behaviors

High-risk social behaviors that would be expected to affect a successful outcome should be identified before surgery. Examples include prior dependence on alcohol or on prescription or non-prescription illegal drugs. The prevalence of these past and current behavior patterns in the general population is significant and cannot be ignored.

Baseline Eating Disorders

Clinical studies indicate that between 0.5% and 1.0% of late adolescent and young adult women meet the criteria for anorexia nervosa, and between 1% and 3% meet the criteria for bulimia nervosa.[92] Eating disorders are multidetermined problems, and they are most commonly recognized among female adolescents. Risk factors may include a perfectionist personality type, a family history of an eating disorder, a history of trauma, a tendency toward feelings of inadequacy, and low self-esteem despite external accomplishments. Patients with eating disorders often exhibit rigid cognitive patterns that are characterized by an all-or-nothing way of thinking.

Orthognathic procedures will significantly alter the diet (i.e., liquids only) and appetite level, with an expected change in nutritional intake for at least 5 weeks. Significant weight loss during the initial 2 weeks of recovery is to be expected, even among healthy individuals. The question is raised as to whether or not these dietary and postsurgical metabolic changes will tend to exacerbate a baseline eating disorder. Maine and Goldberg completed a study to determine if an elective dental manipulation—which, by necessity, results in eating discomfort and dietary restrictions—would likely influence the recovery of or result in a relapse for an individual with a baseline eating disorder.[54] Three questions concerning dental and maxillofacial procedures were added to a standard questionnaire assessment of a consecutive series of 97 individuals who were entering an eating disorder therapy program. The additional questions were designed to determine the influence of dental and maxillofacial interventions on individuals with baseline eating disorders. All 97 study subjects complied with the questionnaire; 75 of the study patients were 25 years old or younger, and 53 were diagnosed with anorexia nervosa.

Interestingly, 9.3% of the study patients who had undergone either significant orthodontic therapy or the removal of the wisdom teeth in the past indicated that the dental procedure—which, by necessity, caused eating discomfort and diet alterations—had either exacerbated or resulted in a relapse of their baseline eating disorders. This study confirms that a history of an eating disorder should alert the orthodontist and the orthognathic surgeon to potential postoperative difficulties. With an awareness of the individual's baseline conditions, the orthodontist, the surgeon, the primary care physician, and members of the psychosocial team may establish guidelines for postoperative behavioral and nutritional objectives to closely monitor to ensure a smooth recovery.

Social Interaction Issues

Ongoing family or social peer conflicts or greater-than-average worries expressed by the individual or his or her family regarding the surgery, the preparation for the surgery, or the anticipated recovery period are red flags.[1,29,33,41] When considering the timing of surgery for the adolescent or young adult, the family should take into account the anticipated impact on the patient's everyday school and social activities, including examination schedules, college applications and interviews, and participation in sports activities. The surgeon's ability to provide a clear picture of the expected recovery time and the patient's ability to return to partial and regular activities is important and will vary according to the patient's age and stage in life (e.g., adolescent, college or graduate student, middle-aged adult with family and work commitments). Clarifying anticipated

postoperative limitations in physical, cognitive, and emotional activities is important to setting the stage for a successful outcome.

Body Dysmorphic Disorder

It is estimated that more than 5% of individuals who are seeking cosmetic surgery consults have body dysmorphic disorder (BDD).[14,19,65,91] BDD is a somatoform disorder that involves a preoccupation with a slight or imagined defect in some aspect of the individual's physical appearance that leads to a significant disruption of daily functions. It is important to distinguish an individual with a legitimate cosmetic or functional concern from one who is hyperconcerned about minor imperfections of some aspect of his or her face.

Cunningham and colleagues documented that a percentage of individuals who request orthognathic surgery will have underlying BDD.[19] A surgical procedure to improve facial aesthetics typically does not change or fully satisfy the appearance concerns of these individuals. Orthognathic procedures may even exacerbate these symptoms, despite the clinician's accurate assessment of the presenting deformity and the likelihood of the achievement of a favorable morphologic and functional result. No matter how skilled the surgeon and how perfect the end result, dissatisfaction should be expected when treating a patient with BDD; therefore, surgery should be avoided unless extensive counseling is performed before the proposed procedure. The development of an effective psychosocial screening interview method or the use of a self-reporting assessment survey to help identify individuals with BDD is needed in clinical practice.

Psychological Functioning in the Individual With a Facial Deformity

A spectrum of studies report that individuals with facial deformities have a higher prevalence of psychological problems that may interfere with the ability of these individuals to function socially. The psychological problems described include (1) a reduced quality of life; (2) a tendency to internalize behavior; (3) low self-esteem; (4) an increased tendency toward depression; and (5) anxiety.[13,100] Interestingly, studies confirm that it is the patient's satisfaction with his or her own appearance rather than an objective standard of the severity of the deformity that influences these psychological problems. The individual's personal dissatisfaction with his or her facial appearance seems to be a better predictor of higher rates of anxiety and depression and lower rates of favorable quality of life and self-esteem as compared with the clinician's impression of how the individual looks.

Versnel and colleagues conducted research that involved adults with facial disfigurement and confirmed that a subset of these individuals demonstrated psychological dysfunctions: 11% had anxiety; 6% had depression; 10% had externalized problems; and 25% had a tendency to internalize problems.[100] The authors clarified that either an actual or a perceived facial deformity can be a significant stressor in life to which the affected individual must adapt.[13,55,72,84,89,93] The study also looked at differences between congenital and acquired facial deformities. Many of the study patients that acquired their facial deformities later in life (i.e., those that were related to trauma or tumors) had a more difficult time, which implied that a significant percentage of those with congenital conditions had eventually adapted to their physical problems. The authors surmised that, because the congenital patients had no knowledge of how life would have been without facial disfigurement, their adaptation was different and often more complete.

An individual's fear of a negative facial appearance evaluation by others during their everyday life is considered a good predictor of psychological functioning. Therefore, psychological support for the individual with either an obvious facial deformity that cannot be further improved or a perceived facial disfigurement should focus on educating the individual to rely less on the opinions of others. From another perspective, surgery carried out for the purpose of enhancing facial appearance must reach or at least approximate the individual's self-perceived expectations. This is the reason why surgery to improve facial aesthetics in the individual with BDD will not result in patient satisfaction; the unrealistic expectations of these patients can never be fully reached.

Patient and Family Decision for or Against the Correction of a Dentofacial Deformity

The patient and the family members or significant others that comprise his or her immediate social network need a clear and consistent explanation of the following:

- The surgical objectives, anticipated treatment outcomes, and limitations with regard to predicting exact results
- How the surgery will fit in with the overall treatment plan (e.g., orthodontics, dental rehabilitation, speech therapy, airway management)
- The potential risks, complications, and limitations of each planned procedure
- What to expect during hospitalization (e.g., discomfort, swelling, hygiene needs, limitations in activity and diet, limitations in mouth opening and lip seal control, difficulties with speech and communication)
- What to expect after discharge from the hospital (i.e., ongoing convalescence needs)
- What the patient and the family must do to maximize a favorable outcome
- When the patient can expect to resume a more normal routine
- The expected time required for full healing

Information should be provided in a number of different ways, which may include (1) verbal discussion; (2) a demonstration of surgical technique on a model skull; (3) showing similar patients' before and after photographs to demonstrate the potential range of results; (4) reviewing and discussing the patient's own photographs, dental models, and radiographs; and (5) providing reinforcement with detailed and readable written material.[32,66] The option of discussing details with another patient of the same approximate age and sex who has undergone similar surgery may also be helpful.

Patient and Family Education Regarding Convalescence After Orthognathic Surgery

Early after surgery, while in hospital, the individual who (1) appears to be more irritable and non-communicative; (2) complains of greater-than-expected levels of pain with demands for continued narcotics; and (3) is having more-than-average difficulty complying with personal care needs (i.e., achieving hydration and caloric requirements, oral and body hygiene requirements, and adequate ambulation) may be a candidate for a demanding convalescence.[77,79] The adolescent may comply just enough (e.g., ambulation, fluid intake) to get out of the hospital. After he or she gets home, unless the parents are able to remain firm concerning patient care needs, the adolescent's feeling of self-consciousness or uncertainty about temporary levels of facial swelling, drooling, loss of appetite, and difficulty with breathing and speech can lead to further social withdrawal and non-compliance. This may also lead to overreliance on narcotic medication with the assumption that pain is the problem. Unless this type of patient is closely monitored, dehydration, hypoglycemia, and depression will set in. Even if this phase of convalescence is managed, some adolescents express unwillingness to return to school within the expected time frame as a result of concern about the reactions of their peers. Many will lose this reluctance when a friend is invited to their home to break the ice. As the recovering patient perceives positive affirmation from their family and friends regarding the changes brought about by surgery, their social hesitation generally subsides.

The clinicians (i.e., the surgeon, the orthodontist, and the treating dentist) often judge success on the basis of measurable standards of (1) an "improved" profile; (2) achieving normative cephalometric radiograph measurements; (3) a corrected occlusion; and (4) achieving specific wound-healing parameters. Discussions with the patient and family should not overlook psychosocial aspects. Individuals with baseline evidence of mental health issues are likely to have a greater-than-average need for positive reinforcement, and they may also require more formal psychological support throughout the perioperative process. The success of treatment should not be thought of solely in terms of improving head and neck function or the achievement of strict numerical parameters. The potential for orthognathic procedures to have profound effects on the individual's psychosocial health—whether positive or negative—should not be underestimated (see Figs. 7-1 through 7-5). During convalescence and after the return to school or work, the clinician should ask the patient about his or her interactions with others regarding the recent surgery to determine if a more in-depth discussion is required.

Patient-Centered Assessment of Surgical and Orthodontic Outcomes

Many public health experts believe that the ultimate determination of a treatment's quality and success is its effectiveness for producing not just physical health as judged by clinicians but also for resulting in the individual's personal satisfaction.[5,22,23,38,44,45,51,56,57,59,82,94,95,98] Traditional surgical outcome measurements such as mortality and improvement in physiologic parameters (e.g., blood pressure) find limited application in the treatment of dentofacial deformities. At the same time, traditional orthodontic parameters of accomplishing specific change in millimeter distances or degrees of angulation at standard anatomic sites do not necessarily correlate with patient satisfaction. Despite the importance of satisfaction as a proxy for quality, the concept of patient-perceived well-being can be difficult to define. When developing a patient questionnaire for use as a self-administered survey after orthognathic surgery, consideration should be given to the features of care that influence the patient's satisfaction. These features may be categorized into one of the following domains: (1) aesthetic outcomes; (2) functional outcomes; or (3) psychological outcomes. A review of the literature concerning patient-centered outcome assessments after orthognathic surgery sheds light on the issue of how to achieve patient-based satisfaction after treatment.

Orthognathic Surgery and Health-Related Quality of Life: Review of Study

Posnick and colleagues reported on data from a health-related quality-of-life survey that was completed postoperatively by a consecutive series of patients who had undergone bimaxillary orthognathic surgery in combination with intranasal and other adjunctive procedures. The survey was filled out by each study patient only after recovery from surgery and after all orthodontic therapy and dental rehabilitation was complete (i.e., a minimum of 6 months after surgery).[82]

A postsurgical patient satisfaction questionnaire was designed by the authors to assess each patient's overall satisfaction with the procedures that he or she underwent, patient-perceived functional improvements, and patient-perceived negative effects. The self-assessment survey was mailed to a consecutive series of 42 individuals who

underwent bimaxillary orthognathic surgery (i.e., Le Fort I osteotomy and sagittal split ramus osteotomies of the mandible) in combination with intranasal (i.e., septoplasty and inferior turbinate reduction) and other patient-specific procedures by a single surgeon (Posnick) at one institution during a 12-month time frame. Patients who underwent orthognathic surgery for the correction of a syndrome, a cleft, or a posttraumatic deformity during the same time frame were excluded from the study. The study group included 15 males and 27 females. The mean age was 25 years, and patient ages ranged from 15 to 55 years. Seven of the 42 patients were less than 18 years old: four were 15 years old, 1 was 16 years old, and two were 17 years old. The most frequent pattern of jaw deformity that was identified in the study group was a long face growth pattern (17 out of 42 patients [40%]), which was characterized as vertical maxillary excess combined with mandibular deficiency. This was followed by primary mandibular deficiency (9 out of 42 patients [21%]). Simultaneous maxillofacial procedures that were completed in addition to those listed previously varied in accordance with patient-specific needs. Thirty-eight percent of the patients (16 out of 42) underwent the simultaneous removal of wisdom teeth. Seventeen percent of the patients (7 out of 42) also underwent suction-assisted lipectomy of the neck. Eighty-six percent of the patients (36 out of 42) underwent osseous genioplasty. The postsurgical patient satisfaction questionnaire made use of a 7-point Likert scale for the respondents to rate their levels of satisfaction or acceptance for each of nine questions that were asked.

To assess overall patient satisfaction three questions were asked. The first question was phrased as follows: "If you had to make the decision again, how likely would you be to undergo this same surgery?" Eighty-three percent (35 out of 42 patients) responded positively to this question; 12% (5 out of 42 patients) were neutral, and 5% (2 out of 42 patients) reported that they would not have undergone orthognathic surgery if they had to do it all over again. The second question was written as follows: "How likely would you be to recommend the same surgery to others?" Two individuals (5%) stated that they would not recommend the same surgery to others. One of the 42 patients (2%) was neutral, whereas 93% of the patients (39 out of 42) stated that they would recommend the same surgery to others. The patients were then asked the following question: "Considering everything, how satisfied are you now with the results of surgery?" Eighty-eight percent (37 out of 42 patients) were satisfied; 1 patient (2%) was neutral, and 4 patients (10%) had at least some degree of uncertainty. These results showed that more than 70% of subjects gave a positive response to all three global satisfaction questions. According to the survey, only 2 out of the 42 consecutive patients (5%) who were treated were dissatisfied (i.e., they answered negatively to all three global satisfaction questions). Interestingly, one of the two dissatisfied patients was judged by the three treating clinicians (i.e., the surgeon, the orthodontist, and the restorative dentist) to have a satisfactory result (i.e., an acceptable occlusion, an improved upper airway, and enhanced facial aesthetics). The second dissatisfied patient developed idiopathic condylar resorption approximately 3 months after surgery, with a resulting residual malocclusion.

The Pearson correlation coefficient highlights several points related to this study group. The global satisfaction questions within the survey (question nos. 1, 2, and 3) all correlate highly with each other. Of the three global satisfaction questions asked, question no. 3 correlates closest with the specific head and neck function questions (question nos. 4 through 9). Of the specific function questions that were asked (question nos. 4 through 9), the perceived residual lip and chin region numbness (question no. 9) had the weakest correlation with overall patient satisfaction. In other words, most individuals were overall satisfied with the results of their orthodontics and orthognathic procedures, despite the fact that they would have preferred a greater return of lip and chin region sensation.

The following question was also asked: "Overall, how satisfied are you with your current bite?" At the completion of treatment, 5 out of 42 patients (12%) were not entirely satisfied with their occlusion, whereas 2% (1 out of 42 patients) gave a neutral response to this question. The majority of patients (36 out of 42 [86%]) expressed satisfaction with their occlusal result after the completion of treatment.

Speech articulation issues are not generally considered a major factor in a patient's decision to undergo jaw surgery. The following question about this issue was asked: "Overall, how satisfied are you with your current speech articulation?" The data suggests that 34 out of 42 patients (80%) were satisfied with their postoperative speech articulation. Nine percent (4 out of 42 patients) had no strong feelings, whereas 4 out of 42 patients (9%) were not completely satisfied with their speech at the completion of treatment.

Patients in this study group were also asked the following: "Overall, how satisfied are you with your current lip posture and lip closure?" Eighty-six percent (36 out of 42) of the patients were satisfied with static lip posture and their ability to actively close their lips. Twelve percent (5 out of 42 patients) were not entirely satisfied; they apparently felt that their ability to control their lips was not completely normal.

The patients were then asked this question: "Overall, how satisfied are you with your current breathing?" Eighty-one percent (38 out of 42 patients) were overall satisfied with their breathing after treatment. Five percent (2 out of 42) were neutral with regard to their assessment of their own breathing, whereas 2 out of 42 patients (5%) remained dissatisfied with at least some aspects of their breathing.

Each patient was asked the following question: "Overall, how accepting are you with your current level of TMJ [temporomandibular joint] function/facial pain?" Eighty-eight percent (37 out of 42 patients) were accepting of their current TMJ function and of any degree of facial pain that they may have. Five percent (2 out of 42 patients) were

neutral about this issue, whereas 3 out of 42 patients (7%) were not completely accepting of their level of TMJ dysfunction or facial pain after treatment.

Patients were asked to respond to the following question: "Overall, how accepting are you with your current level of lower lip/chin sensation?" This question registered the highest level of patient dissatisfaction. Twenty-one percent of patients (9 out of 42) wished that their postsurgical sensory loss was not as much. Twenty-four percent of patients (10 out of 42) were neutral on this issue, whereas 23 out of 42 (55%) were accepting of their level of lower lip and chin region sensory return after treatment.

Controversies Surrounding "Successful" Orthognathic Outcomes

Interestingly, although 5 out of 42 (12%) of the patients studied by Posnick and colleagues were not completely satisfied with their occlusions, only 2 out of 42 (5%) of the patients were dissatisfied with the overall experience of having undergone the orthognathic procedures and the orthodontic treatment. Therefore, it is apparent that the occlusion achieved is not the only and not even the most important factor when a patient is judging surgical success or failure. Posnick's study group data also showed that, despite the fact that 21% (9 out of 42) of the patients were not entirely comfortable with the degree of sensory return to the lower lip and chin region, only 5% (2 out of 42) were dissatisfied with the postoperative surgical results overall.

Not surprisingly, orthognathic surgery patients' self-verification needs (i.e., the need to feel accepted) are generally an important factor in their judgment of successful treatment. This need cannot be overlooked if a favorable result is to be achieved.* For example, patients who undergo orthognathic procedures may expect to draw attention to their new appearance. If orthodontic treatment and orthognathic surgery result in positive and praising feedback from those in their social circles, self-verification is fulfilled, and they are likely to be satisfied. Some orthognathic patients may have realistic expectations but do not have a supportive social network of family and friends to fulfill their self-verification needs. Negative appearance–related commentary (e.g., teasing by peers at school, or more subtle forms of negative feedback by adults) has been shown to significantly affect body image and psychosocial functioning after surgery. If the comments of others are not positive or do not meet personal expectations (which can be unrealistically high), self-verification needs are not fulfilled, and the patient is likely to be dissatisfied. One concrete self-verification need after orthognathic surgery is a "normal" occlusion. The feedback that an individual receives from his or her treating clinicians (i.e., the orthodontist, the restorative dentist, and the surgeon) about his or her occlusion would be expected to influence that individual's level of satisfaction.

Kiyak and colleagues completed a study that evaluated the psychological changes in patients who were undergoing orthognathic surgery.[46-51] They used a standardized questionnaire before and at intervals that extended for 2 years after surgery. The data for all six measurement periods (2 weeks preoperatively, in the hospital, and 2 weeks, 4 months, 8 months, and 2 years postoperatively) were available for 46 patients. Several important findings from this research included the following:

1. Complaints of functional head and neck problems decreased significantly from before surgery to 24 months after surgery.
2. A significant percentage of patients (49%) continued to report lip paresthesia 2 years after surgery.
3. The incidence of early postsurgical problems or complaints (i.e., at 2 weeks) had no consistent effect on the satisfaction expressed with longer-term surgical outcomes (i.e., at 2 years).
4. The satisfaction expressed by patients with surgical outcomes at 4 months remained high throughout the postoperative course (i.e., at 2 years).
5. Self-esteem appeared to rise in anticipation of surgery (i.e., at 2 weeks preoperatively) but to decline at 8 months after surgery. The patients' self-esteem then rose again as documented at 24 months after surgery. Interestingly, on average, self-esteem never reached the high expectations of the surgical outcome that the patients had expressed at 2 weeks before surgery.
6. Body image showed a decline at 9 months after surgery as compared with its highest point. Fortunately, the overall body image at 2 years after surgery was significantly more positive than it was at 2 weeks before surgery.

On the basis of this data, Kiyak's group suggests that, if feasible, clinicians should maintain periodic contact with their orthognathic surgery patients for at least 2 years after surgery.[46-51] Although clinician interactions with the patient immediately after surgery generally fall to the surgeon (i.e., at 0 to 5 weeks), during the intermediate stage after surgery (i.e., 1 to 12 months), clinician feedback primarily falls to the orthodontist and the general dentist. According to the study, at 6 to 12 months after surgery, psychological unevenness for the patient is not uncommon. The patient and the orthodontist may experience conflict regarding the importance of "finishing the bite" and the timing of the completion of treatment. The patient may become adamant that the braces be removed for a specific social event (e.g., graduation, yearbook photographs), whereas the orthodontist may wish to continue detailing the bite. The orthodontist may focus on dental aspects that are considered to be of less immediate importance from the patient's perspective. At the same time, the patient may have concern about persistent paresthesia (i.e., of the inferior alveolar and infraorbital

*References 7, 11, 15, 20, 28, 30, 31, 35, 36, 39, 40, 43, 47-50, 52, 60, 62, 70, 74, 85, 88, 90, 99

nerves) and whether this is a complication or an expected consequence of the jaw surgery. If accurate information was given before surgery and if the lines of communication remain open between the patient and the surgeon, a favorable resolution of this issue is likely. The orthodontist should be aware of the expected progression of sensory recovery and suggest a return visit to the surgeon if he or she perceives a potential conflict. If instead the orthodontist, the restorative dentist, or the office personnel (e.g., the hygienist, the dental assistant) make off-the-cuff disparaging remarks about the patient's facial aesthetics, occlusion, or incomplete facial sensory return, then the patient may assume the worst.

At the conclusion of their study (i.e., 24 months after surgery), Kiyak and colleagues found that a majority of patients had achieved their personal dental (occlusal) or jaw function objectives.[46-51] Nevertheless, a minority of the subjects continued to have lingering concerns. If the patient perceived that the facial aesthetic improvements did meet his or her personal expectations, then overall satisfaction was high, regardless of any residual functional complaints (e.g., paresthesia, dysesthesia, temporomandibular disorder, occlusal imperfection). The majority of the orthognathic patients in the study by Kiyak and colleagues did in fact perceive facial aesthetic improvements and were therefore pleased.

The authors made several suggestions. First, it is helpful to prepare patients thoroughly before surgery and to explain not just the temporary functional impairment that they will experience soon after surgery but also the psychological changes toward themselves and toward others that are to be expected throughout recovery. Second, it is important to emphasize that these changes will likely continue to evolve for as long as 2 years after surgery. Third, if the patient is unprepared for the anticipated facial aesthetic changes, then dissatisfaction is also more likely. For these reasons, both the surgeon and the orthodontist should maintain open lines of communication with the patient and each other long after primary skeletal healing has occurred. Anticipating the persistence of lower lip and chin paresthesia as a consequence of the mandibular osteotomies should be communicated clearly during the preoperative discussion and then reinforced at several postoperative intervals.

Lee and colleagues completed a study to evaluate the patient-centered assessment of health at 6 weeks and then 6 months after orthognathic surgery.[53] Their 36 study patients were evaluated at intervals that included baseline/presurgery; 6 weeks postoperatively; and 6 months postoperatively. A standardized health-related survey was given at each time interval. The results of this study demonstrated a significant deterioration in both the physical and mental health of the patients soon after surgery (at 6 weeks) as compared with baseline. This matches the expected signs and symptoms that are typically observed soon after surgery. At 6 months after surgery, there was a statistical return to baseline levels in combination with significant improvements in several of the parameters that were measured. The authors concluded that significant positive changes in quality of life occurred after orthognathic surgery in the majority of patients when their healing was complete. There was a marked but transient deterioration in many aspects related to physical and emotional well-being during the early postoperative period (i.e., the first 6 weeks after surgery). This was followed by significant improvements that were documented by 6 months after surgery.

In a discussion of their results, Lee and colleagues stated that patients who report unexpected negative effects after surgery are more likely to be dissatisfied with their overall treatment. Soon after surgery, Lee's group documented difficulties with the orthognathic patient's ability to carry out daily physical activities, work performance, and social activities with friends and family. Patients experienced moderate degrees of pain, tiredness or lack of energy, and emotional impairment during the early recovery period. All of these changes are predictable and temporary, and they should be explained to the patient and the patient's family before surgery and then reinforced during the postoperative visits. It was found that, even during the early recovery period (i.e., the initial 6 weeks), as long as reasonable preoperative education was provided, there is generally improvement in the patient's psychological status. The authors believe that this is a reflection of the patient's perceived improvements in both occlusion and facial appearance meeting his or her personal expectations despite difficulties experienced as part of the normal healing process. By 6 months after orthognathic surgery, there was a trend toward further improvements in emotional well-being. By then, the overall study group consciously experienced marked improvements in facial aesthetics, oral and jaw function, and social abilities.

Conclusions

A review of the literature regarding patient satisfaction after orthognathic surgery confirms the need for the following: (1) careful preoperative patient selection; (2) clear communication of realistic and agreed-upon objectives; and (3) including the family or the immediate social network and all collaborating clinicians in the process. Although the majority of patients and their families will be pleased with the results that are achieved, a small percentage will be dissatisfied, despite the clinician's perception that the results achieved were at least an improvement and even when no specific complications occurred. In addition, as with any form of treatment or surgery, complications may occur despite the best of care. Until the science of patient selection parallels clinical realities, anticipating a small percentage of dissatisfied patients and families remains the norm. The meticulous documentation of the interactions between the patient and the doctor as well as the maintenance of open lines of communication between the patient and all treating clinicians beyond the initial healing period remain essential components of patient management when performing orthognathic procedures.

Speech, Mastication, and Swallowing Considerations in the Evaluation and Treatment of Dentofacial Deformities

JEFFREY C. POSNICK, DMD, MD

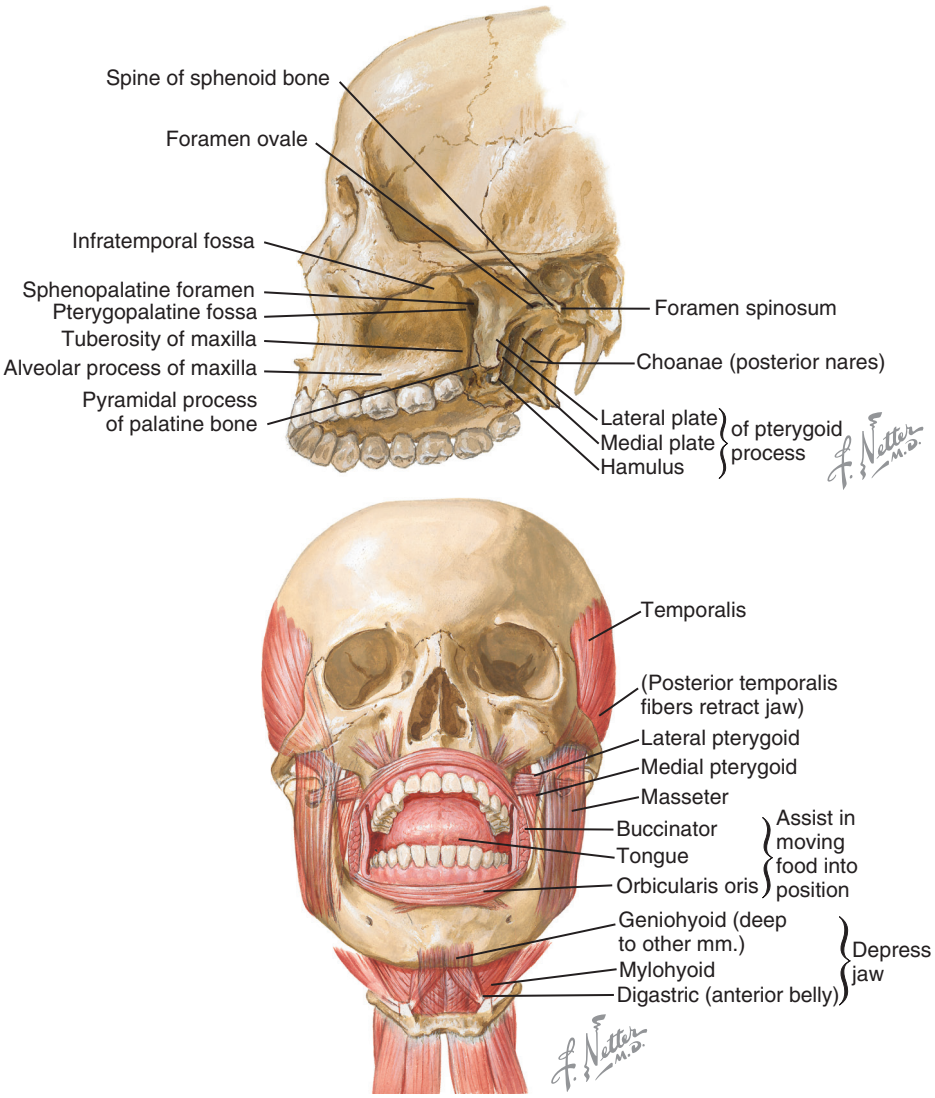
- The Neuromuscular Masticatory System
- Mastication Mechanism
- Swallowing Mechanism
- Speech: Mechanism, Formation, and Assessment
- Effects of Jaw Deformities with Malocclusion on Speech
- Effects of Successful Orthodontics and Orthognathic Surgery on Speech
- Conclusions

The physiologic and functional mechanisms of human speech, mastication, and swallowing are essential for an individual to maintain his or her normal performance levels. These are highly coordinated and complex actions that are closely interrelated. These functions are susceptible to physical impairments, such as the presence of a dentofacial deformity. This chapter will review the mechanisms of normal speech, mastication, and swallowing. The potential for negative sequelae that stem from the presence of a jaw deformity with malocclusion and the benefits of successful reconstruction are also reviewed.[11,151]

The Neuromuscular Masticatory System

The *masticatory system* is an integrated complex that is primarily made up of bones, muscles, ligaments, and teeth. Movement of the structures is neurologically coordinated for efficient function and for the maintenance of the component parts over the individual's lifetime.[1-3] Controlled contracture and relaxation of the head and neck musculature are necessary to move the mandible, the soft palate, the lips, and the tongue efficiently for effective function (i.e., speech, swallowing, and chewing). A neurologic control system regulates and coordinates the activities of the entire masticatory system.

The dynamic balance of muscles in the head and neck is made possible through feedback that is provided by sensory receptors.[10] To create a precise mandibular movement, input from the various sensory receptors is received by the central nervous system through the afferent fibers.[41] The brain stem and cortex work together to assimilate and organize this input, and then provide modulated motor activities through the efferent nerve fibers.[80] Within the brain stem, neurons control rhythmic muscle activities for effective breathing, swallowing, and chewing.[25] These neurons are called the *central pattern generator* (CPG).[96] The CPG is responsible for the timed and integrated activity among antagonistic muscles that is needed to accomplish these functions. For example, during chewing, the suprahyoid and infrahyoid muscles contract at the same time that the elevator muscles relax; this allows the mouth to open and accept food. With the bolus of food in the mouth, the CPG causes contraction of the elevator muscles while relaxing the suprahyoid and infrahyoid muscles, thereby producing closure of the mouth onto the food bolus. This chewing mechanism is repeated until the particles of food are small enough to be efficiently swallowed. All of this assumes that the individual has normal functioning of the tongue and lips, adequate numbers and locations of teeth, and intact temporomandibular joints and jaws (Fig. 8-1).[43] Ideally, with all of these component structures in place, chewing can be accomplished without excess stress to any of the component parts. Although chewing is typically a subconscious activity, it can be brought into conscious control at any time. Likewise, breathing and swallowing are generally carried out as subconscious activities, but they can also be brought under voluntary control to be refined (Table 8-1).



• **Figure 8-1** Mastication is the process of chewing food in preparation for deglutition (swallowing) and digestion. All muscles of mastication originate on the skull and insert on the mandible. All muscles of mastication are innervated by the mandibular division of the trigeminal nerve. All muscles of mastication are derivatives of the first pharyngeal arch. Movements of the mandible are classified as follows:

- Elevation
- Depression
- Protrusion
- Retrusion
- Side-to-side (lateral) excursion

The bones involved include the base of the skull and the mandible. The skull base and the mandible articulate at the temporomandibular joint between the squamous portion of the temporal bone and the condyle of the mandible.

The muscles involved in the masticatory process include four paired muscles:

- The masseter
- The temporalis
- The medial pterygoid
- The lateral pterygoid

Although the buccinators are not strictly considered muscles of mastication, they help to keep the bolus of food against the teeth during this process. The illustrations shown here demonstrate the masticatory muscles' bony insertions and locations of insertion as well as their overall anatomy. *Netter illustration from www.netterimages.com* *© Elsevier Inc. • **Figure 8-1, cont'd**

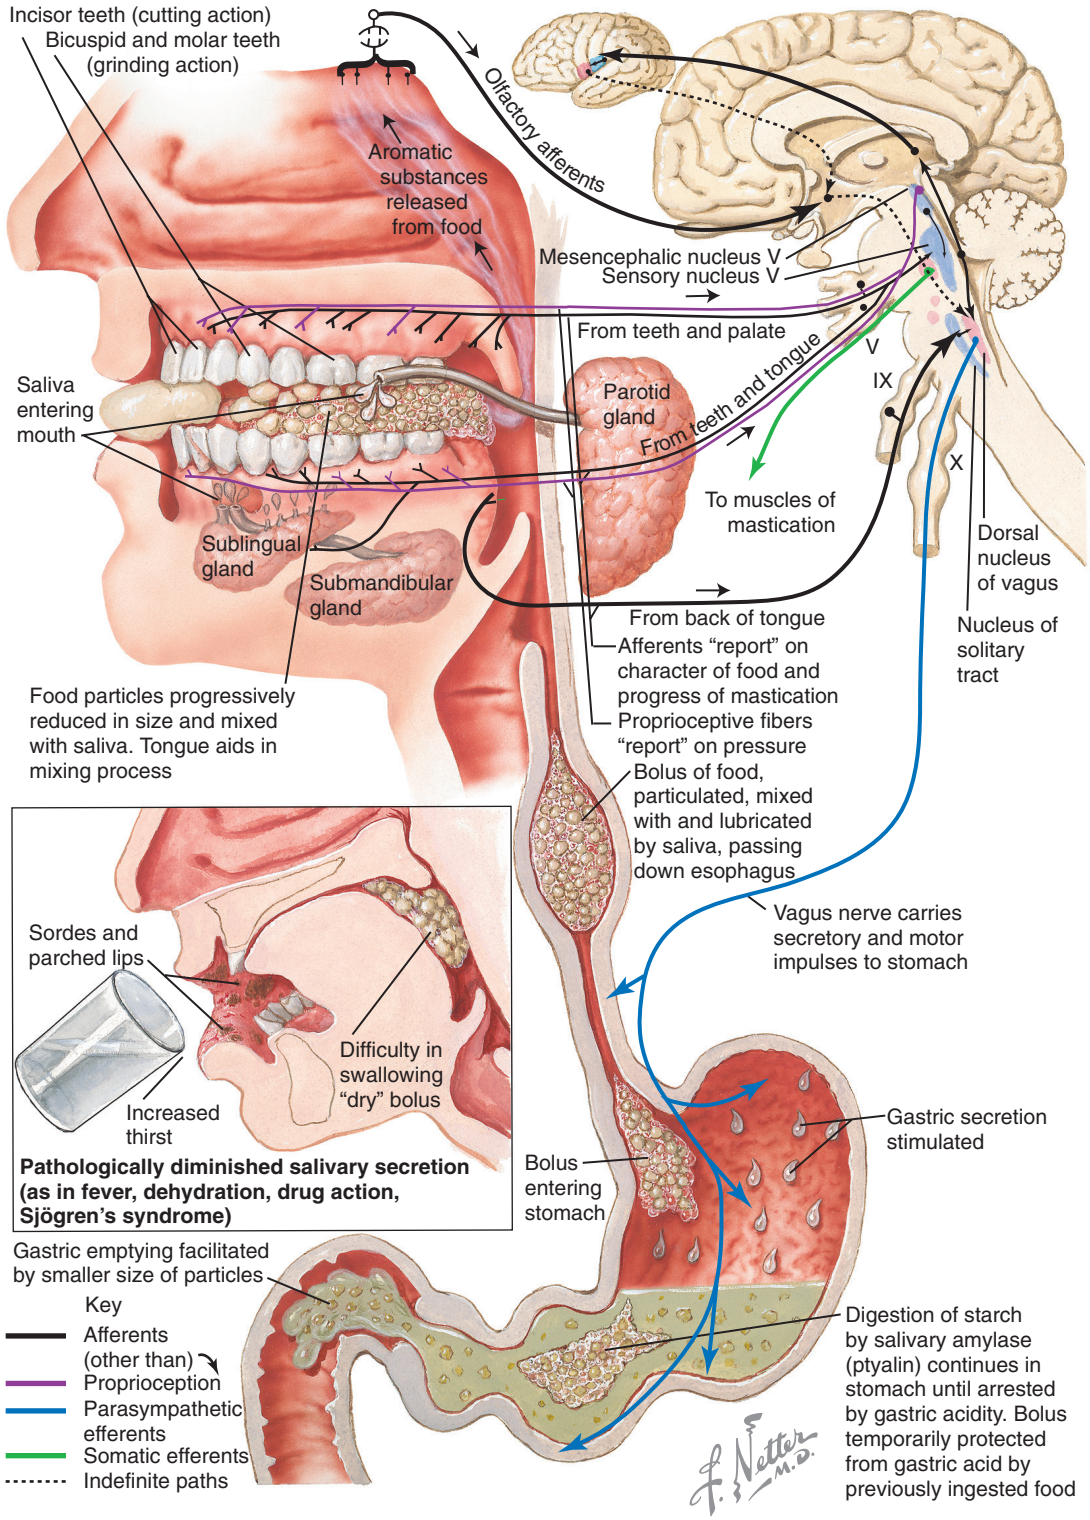
TABLE 8-1 Muscles of Mastication

Muscle of Mastication	Origin	Insertion	Main Actions
Masseter: superficial head	• Inferior border of the anterior two thirds of the zygomatic arch	• Angle of mandible • Inferior and lateral parts of the mandibular ramus	• Elevates mandible • Protrudes mandible • Aids in lateral excursion of mandible
Masseter: deep head	• Medial border of the zygomatic arch • Inferior border of the posterior one third of the zygomatic arch	• Superolateral mandibular ramus • Coronoid process	
Temporalis	• Temporalis fossa, along the inferior temporal line, including the temporal fascia	• Coronoid process, extending inferiorly on the anterior border of the mandibular ramus	• Elevates mandible • Protrudes mandible • Aids in lateral excursion of mandible
Medial pterygoid: deep head	• Medial surface of the lateral pterygoid plate	• Medial surface of the ramus and the angle of the mandible	• Elevates mandible • Protrudes mandible • Lateral excursion of mandible
Medial pterygoid: superficial head	• Maxillary tuberosity	• Medial surface of the ramus and the angle of the mandible	• Elevates mandible • Protrudes mandible • Lateral excursion of mandible
Lateral pterygoid: upper head	• Greater wing of the sphenoid • Infratemporal crest	• Articular discs and the capsule of the temporomandibular joint	• Depresses mandible • Protrudes mandible • Lateral excursion of mandible
Lateral pterygoid: lower head	• Lateral surface of the lateral pterygoid plate	• Pterygoid fovea on the neck of the condyle	• Depresses mandible • Protrudes mandible • Lateral excursion of mandible

Mastication Mechanism

Mastication is defined as the act of chewing food (Fig. 8-2). It represents the initial stage of digestion. During mastication, the food bolus is broken down into small particles for ease of swallowing. For most, it is considered an enjoyable activity that involves the senses of taste, touch, and smell. It is a complex function that requires the involvement of the muscles, the teeth, and the periodontal supportive structures. It also requires functioning temporomandibular joints and jaws, and it makes use of the lips, the cheeks, the tongue, the palate, and the salivary glands. It is an activity that is usually automatic and often taken for granted, although it can be easily brought into voluntary (i.e., conscious) control. It is also susceptible to pathologic conditions and damaging habits. Furthermore, modifications of this system (i.e., compensatory patterns) will be introduced when component parts are not in proper working order (e.g., in the presence of dentofacial deformity with malocclusion).

In the normal setting, mastication is made up of rhythmic, well-controlled separations and closures of the maxillary and mandibular teeth. This activity is under the control of the CPG, which is located in the brain stem. Each opening and closing movement of the mandible represents a chewing stroke.[79] The *chewing stroke* can be divided into the *opening phase* and the *closing phase*. The closing phase may be further subdivided into the *crushing phase* and the *grinding phase*. During mastication, the chewing stroke is repeated until the food is broken down into small enough parts for swallowing. After the food has been incised (usually with the anterior teeth) and then brought further into the mouth, the crushing of the bolus is concentrated on the posterior teeth.



• **Figure 8-2** Mastication prepares food via "chewing" for deglutition and digestion. The illustrations and legends show an overview of the process. *Netter illustration from www.netterimages.com* *© Elsevier Inc. All rights reserved.*

It has been documented that the tooth contact ability, the number of teeth, and the quality of the teeth influence the chewing stroke. During mastication, sensory information is sent back to the central nervous system.[5,158] This feedback mechanism allows for the alteration of the chewing stroke in response to the particular food being chewed and the quality of the anatomic structures that are available for chewing.[65] Generally, with maximum full intercuspation (i.e., tall cusps, deep fossae, and ideal contacts), a predominantly vertical chewing stroke is seen. When there is a flattened occlusal surface (e.g., as a result of occlusal equilibrium or a grinding habit that involves a loss of enamel), a broader chewing stroke can be documented.[54,81] The presence of malocclusion may produce irregular and less repeatable chewing strokes in the individual.[6] Studies document that, in approximately 75% of subjects, there is a preferred chewing side.[6] Chewing activities normally occur on the side with the greatest number of pain-free tooth contacts noticed during lateral glide.

The maximum biting force that can be applied to the teeth varies from individual to individual.[156] With tougher foods, chewing preferably occurs predominantly on the first molar and second premolar areas. In general, males can bite more forcefully than females. Typically, in the presence of normal anatomy, the maximal amount of force applied to a molar is several times that which can be applied to an incisor.[60] The maximum biting force generally increases with age, up to adolescence. Nevertheless, the amount of force placed on the teeth during mastication varies greatly from individual to individual.[103,114]

When food is introduced into the mouth, the lips must guide and control intake. After the food is in place, the lips must seal off the oral cavity. The lips are especially necessary when liquid is being introduced.[58] This is more difficult for the individual with a long face growth pattern that causes mentalis strain and lip incompetence. When the food is in the mouth, the tongue plays a major role in maneuvering the bolus for sufficient chewing. The tongue typically initiates the process of breaking up the food by pressing the bolus against the hard palate; thus, the presence of an oronasal fistula in a patient with a cleft palate can be problematic. The tongue then pushes the food onto the occlusal surfaces of the teeth, where it can be effectively crushed during the chewing stroke. During the opening phase of the next chewing stroke, the tongue repositions the partially crushed food again onto the teeth for further breakdown. While the tongue is repositioning the food that has been displaced lingually, the buccinator muscle in the cheek region is compressing the food that has shifted into the vestibule back over the molars. The displaced food is continuously repositioned on the occlusal surfaces of the teeth until the particles are small enough to be swallowed efficiently. The tongue is also used to separate the food particles that require more chewing (and are therefore replaced over the molars) from those that are now small enough for swallowing. This sorting process is essential to prevent choking on large food particles. After the eating process is complete, the tongue is used to clean the teeth and to remove any food residue that has been trapped in locations such as the floor of the mouth (i.e., the sulcus) or in the labial vestibule.

In the presence of normal anatomy, the ingestion of a bolus of food is made easier by the active lowering of the mandible, the opening of the lips, and the depression of the tongue.[25] All of these activities increase the size of the oral cavity to accommodate the bolus that is to be ingested. Not surprisingly, temporomandibular joint ankylosis or masticatory muscle pain with trismus will limit mouth opening and alter the process. The ingestion of fluid is usually via sucking (e.g., with a straw). In this case, the lips remain sealed around the delivery device, and the exit to the back of the oral cavity is closed by the tongue and the soft palate. In the individual with a long face growth pattern (i.e., lip incompetence and an anterior open bite), this will be more difficult. The lowering of the mandible and the depression and retraction of the tongue are accomplished by bracing the cheeks laterally and the mouth floor inferiorly. These actions will generate a subatmospheric pressure within the oral cavity to facilitate the flow of fluids into the oral cavity. This process will be more difficult in the presence of an oronasal fistula (i.e., an incompletely repaired cleft palate). This form of suction is also a useful mechanism for driving the entry of saliva into the oral cavity from the salivary glands.[112]

Swallowing Mechanism

Swallowing is a process that occurs through a series of coordinated muscular contractions that move the bolus of food from the oral cavity through the esophagus and into the stomach (Fig. 8-3). It requires voluntary, involuntary, and reflex muscular activity. The decision to swallow generally depends on the following: (1) the degree of fineness of the food (2) the intensity of the taste extracted and (3) the degree of lubrication of the bolus. During the swallowing mechanism, the lips are closed to seal the anterior aspect of the oral cavity. The teeth are brought into their maximum intercuspal position for the stabilization of the mandible. With the mandible fixed, the contraction of the suprahyoid and infrahyoid muscles will control the movement of the hyoid bone for effective swallowing.

The normal adult swallow involves the use of the teeth for mandibular stability; this is called the *somatic swallow.* When adequate teeth are not present (e.g., in the infant), the mandible must be braced by other means. In the infant swallow, which is also called the *visceral swallow,* the mandible is braced by placing the tongue between the dental arches.

In the normal growing child, as the posterior teeth erupt, the occluding teeth are able to brace the mandible, and the transition to an adult swallow occurs. In the presence of malocclusion, either from a developmental jaw deformity (i.e., an anterior open bite or a Class II malocclusion with significant overjet) or from the loss of teeth from either

tumor or trauma, the infant swallow is maintained or reassumed (Fig. 8-4). In the presence of an anterior open bite, it is necessary for the individual to thrust the tongue forward to close the gap during the swallowing mechanism. This is an appropriate *compensatory swallowing pattern*.

Studies confirm that this repetitive *swallowing cycle* occurs approximately 600 times during a 24-hour cycle in the average individual.[33] The general breakdown includes cycles during eating, cycles between meals while awake, and cycles during sleep. Lower levels of salivary flow during sleep result in less need for swallowing.[112]

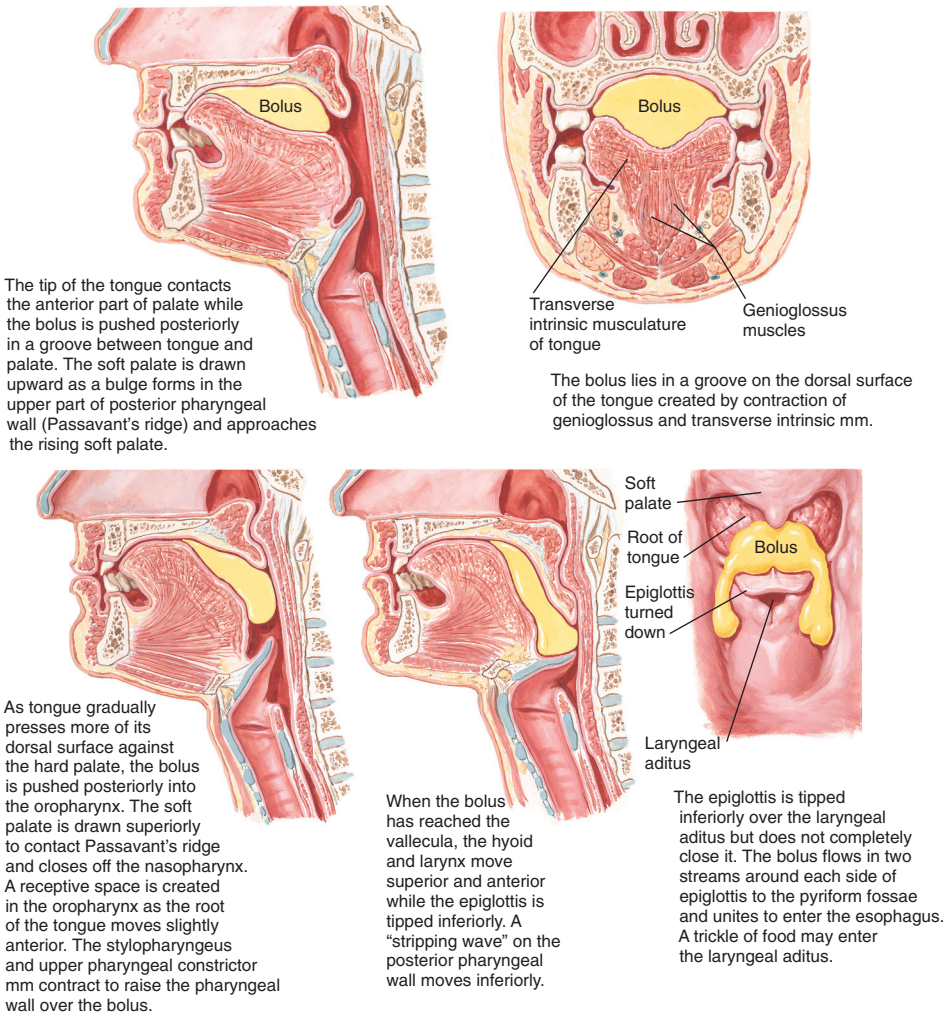
Although swallowing is one continuous act, for descriptive purposes, it is divided into three stages.

Swallowing: First Stage

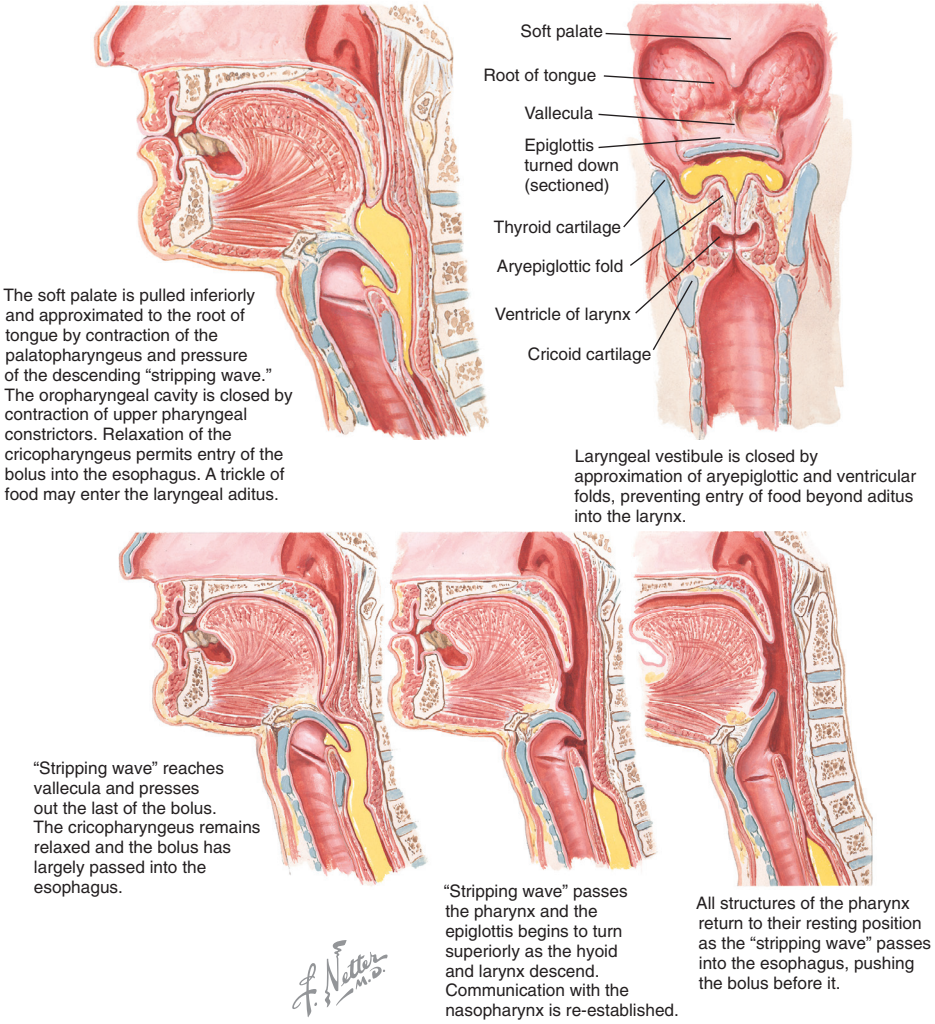
The first stage of swallowing is voluntary. It begins with the selective separation of the masticated food into a specific bolus. This task is accomplished primarily by the tongue. The bolus is positioned on the dorsum of the tongue and then pressed lightly against the intact hard palate. The tip of the tongue rests on the hard palate anteriorly, just behind the incisors. The lips are sealed, and the teeth are brought together; this essentially dams off the anterior oral cavity. The presence of the bolus pressed against the mucosa of the intact hard palate initiates a reflex wave of contraction of the tongue that pushes the bolus backward. As the bolus reaches the back of the tongue and with the soft palate now occluding against the nasopharynx, the bolus is transferred into the pharynx.

Swallowing: Second Stage

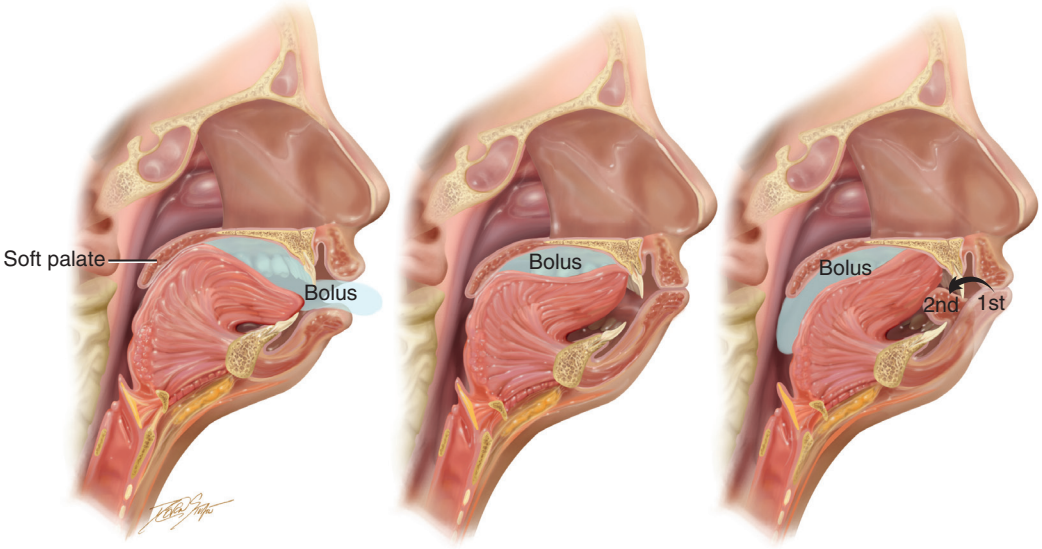
When the bolus has reached the pharynx, a peristaltic wave caused by the contracture of the pharyngeal constrictor muscles carries it down the pharynx. To prevent regurgitation into the nasal cavity, the soft palate must rise and touch the posterior pharyngeal wall, thereby sealing off the nasal



• **Figure 8-3** Deglutition or swallowing is a combination of voluntary and involuntary muscle contractions that move a bolus of food from the oral cavity to the esophagus. These illustrations review the details of the process. *Netter illustration from www.netterimages.com © Elsevier Inc. All rights reserved.* *Continued*



• **Figure 8-3, cont'd**



• **Figure 8-4** Illustrations of a compensatory swallowing mechanism in an individual with a Class II excess overjet malocclusion. This illustration is representative of the patient shown in Figure 8-10.

cavity. Simultaneously, the epiglottis must block the pharyngeal airway to the trachea to prevent the food from going into the larynx or the trachea and ending up in the lungs. This process of walling off potential openings keeps the food moving down the esophagus. During this stage of swallowing, the pharyngeal muscular activity opens the pharyngeal orifices of the eustachian tubes, which would otherwise be closed.

Swallowing: Third Stage

The third stage of swallowing describes the passing of the bolus through the length of the esophagus and into the stomach. Rapid peristaltic waves carry the bolus through the esophagus. As the bolus reaches the lower esophagus, the sphincter relaxes, thereby allowing for the entrance of the bolus into the stomach. Interestingly, in the upper portion of the esophagus, the muscles are mainly voluntary and can also be used to return the bolus into the mouth when necessary for more complete mastication. In the lower section of the esophagus, the muscles are entirely involuntary.

Evaluation of Swallowing

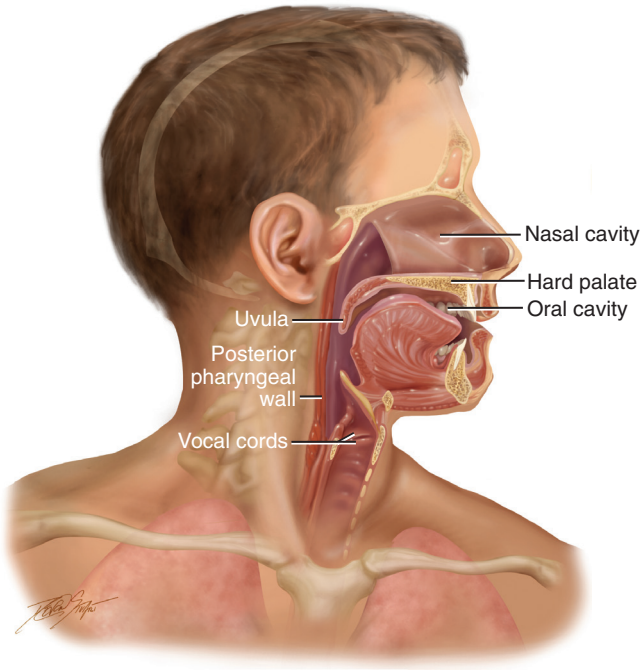
When a complaint about swallowing is registered, a special evaluation may be required. Such an evaluation should consist of a complete medical history, a detailed description of the complaint, and a physical examination of the peripheral deglutitory motor and sensory system, including trial swallows under observation. Diagnostic studies—including videofluorography, manometry, electromyography, and fiber-optic endoscopy—are indicated in selected cases.

Speech: Mechanism, Formation, and Assessment

The *mechanism of speech* is composed of several highly integrated processes (Fig. 8-5)[26,31,122]:

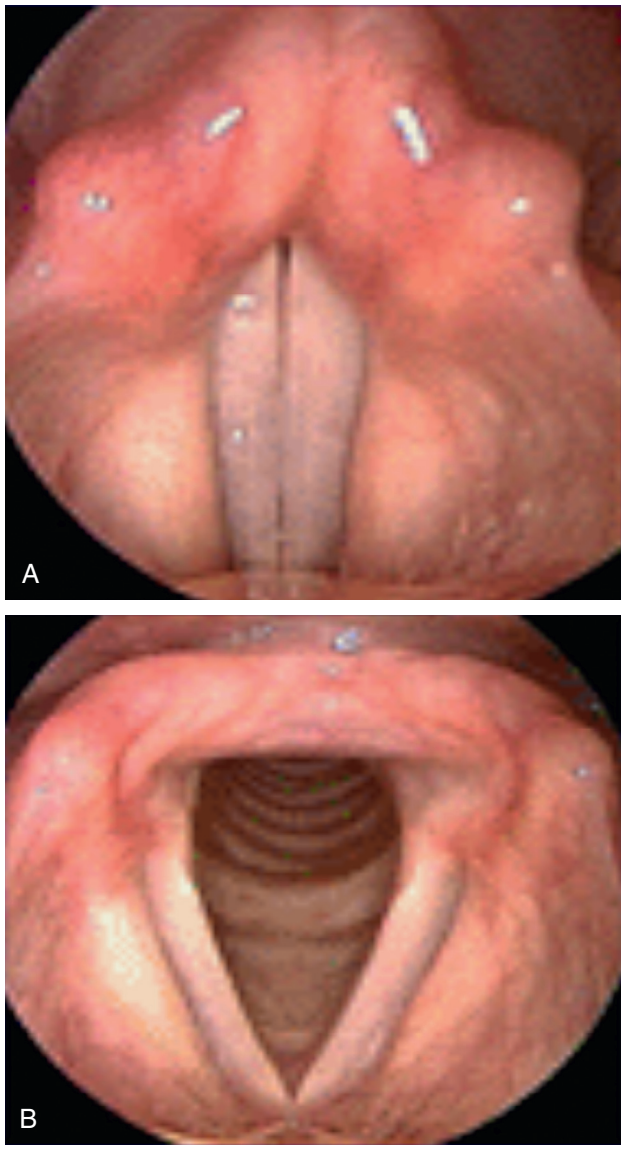
- *Speech initiation,* during which the content of the utterance to be spoken is converted into phonemes in the brain's language center
- The *generation of commands* that go from the brain's motor center to the speech organs
- *Phonation,* during which the emission of air sent from the lungs moves through the vocal tract and causes the formation of the voice as it moves past the vocal folds
- *Articulation,* which involves movement by the oral cavity, the oral pharynx, and the hypopharynx for the production of speech via this specific set of motor commands

During *human speech production,* the airflow that is sent from the lungs with a constant pressure passes between the vocal cords; the vibration of the vocal cords causes the airflow to be converted into cyclic puffs of air that then become sound (Fig. 8-6). The airstream is interrupted by movements of the jaws, the tongue, the soft palate, and the lips. These movements change the shape of the vocal tract, which in turn enables the individual to control the articulated sound and resonance characteristics.[4] The *pitch* of the voice changes in accordance with adjustments that are made in the tension of the vocal cords. *Voiced sounds* incorporate the vibration of the vocal cords in addition to the placement of the articulators. *Unvoiced sounds* are produced by the interruption of the airstream by the articulators. Voiced sounds are produced with vocal fold vibration that accompanies articulator placement. *Vocal tract resonance* characteristics are controlled by the cross-sectional area of various parts of the vocal tract.[36] Examples include the articulation of the upper lip to the lower lip for the bilabial sounds of /p/, /b/, and /m/ and the articulation of the tongue to the alveolar ridge for the production of the lingual-alveolar sounds /t/, /d/, /n/, /l/, /s/, and /z/.[120]



• **Figure 8-5** Illustration of a cross section through the head and neck that shows the pertinent anatomy required to articulate speech.

Individual articulators (i.e., upper jaw, lower jaw, upper lip, lower lip, tongue, soft palate, hard palate, upper teeth, and lower teeth) are used for both the speech mechanism (Figs. 8-7 and 8-8; Table 8-2) and for the mastication and swallowing (deglutition) mechanisms (see Figs. 8-1, 8-2, and 8-3).[123] *Speech sounds* are composed of the approximation of individual articulators within the speech mechanism and the manner in which the airflow from the vocal cords is modulated.[59] This in turn produces what is called a *phoneme,* which is known to most as an isolated speech sound. A significant feature of articulatory movements is the phenomenon of *assimilation* in which the mouth position for an *individual phoneme* in the *utterance*



• **Figure 8-6** A view of vocal cords as seen via nasoendoscopic examination. **A,** Closed vocal cords (adduction position). **B,** Open vocal cords (abduction position).

incorporates the effects of the mouth position for the phonemes uttered immediately before and after. Interestingly, a human can imitate the sound of an utterance that he or she has heard without necessarily being able to speak the language of the utterance.[66] In other words, the individual can estimate which mouth movements are necessary to produce a sound that is similar to the one that he or she has heard. By convention, the classification of speech sounds is categorized in accordance with their manner and place of production (i.e., the location of articulation).

Vocal tract variables include the dynamic voluntary movements of the *vocal organs* (e.g., lower jaw, tongue, soft palate, vocal cords, upper lip, lower lip); these organs and their movements are influenced by the basic positions of the organs in relation to each other. The baseline position of the jaws and teeth vary widely; however, if they are significantly displaced (i.e., if there is malposition of the teeth or jaws), this can negatively affect articulation (Fig. 8-9). When the position of a jaws is abnormal (i.e., dentofacial deformity) and then successfully corrected via orthodontics and orthognathic surgery, including a return of normal morphology, then the tongue may or may not respond instantaneously to achieve a more normal utterance of specific consonant or vowel sounds (see Fig. 8-8).

In general, in the patient with a dentofacial deformity, the articulators will try to adapt first to the genetically malpositioned jaws and teeth and then to the corrected anatomy after successful orthodontics and orthognathic surgery. It is said that the tongue is the single most important articulator, because it is highly mobile and therefore adaptable to the adjacent vocal organs for the production of a spectrum of speech sounds, even when the other articulators are abnormally located (e.g., as a result of the malposition of the teeth and jaws, a palatal fistula, a poorly moving velum, or widely separated lips). The *vocal folds* also have the capacity to adapt when speech pressure leaks out of the nose. The upper and lower lips, the soft palate, and the mandible are also mobile but to a more limited degree; therefore, they are less adaptable components of the vocal tract.

Speech sounds are generally divided into the categories of *consonant sounds* and *vowel sounds.* The production of consonant sounds requires the obstruction or partial closure (i.e., sphincteringe) of the airstream at specific sites along the vocal tract.[121] The classifications of consonant sounds are based on the extent of airstream obstruction, the site of airstream obstruction, and whether the vocal cords vibrate.[16,17] Vowel sounds are generally produced by the position of the tongue and lips without airstream obstruction and with the upper and lower teeth more widely separated. All vowel sounds are voiced, and it is for this reason that vowel sounds are generally less affected by the malpositioning of the teeth or jaws than consonant sounds are.[138]

With regard to the consonant sounds, the different extents of airstream obstruction are generally considered to fall into the following categories:

- *Plosive/stop:* Air pressure is stopped within the oral cavity at a specific location, and it is then suddenly released. Examples are /p/, /b/, /t/, /d/, /k/, and /g/.
- *Fricative:* Air pressure is partially blocked or obstructed within the vocal tract, thereby causing turbulent airflow. Examples are /f/, /v/, /s/, and /z/.
- *Affricative:* There is a sequencing of the airstream initially with complete obstruction (i.e., plosive/stop) followed by fricative (i.e., partial vocal tract obstruction) at the same location. Examples are /ch/ and /j/.
- *Nasal:* Air is allowed to pass freely through the nasal cavity. Examples are /m/, /n/, and /ng/.

The anatomic locations of the vocal organs that block or partially block the airflow (i.e., places of articulation) include the following: bilabial (upper lip to lower lip);

TABLE 8-2 Kinesiologic Positions for the Oral and Pharyngeal Musculature during the Articulation of Speech Sounds

Structural Components of the Articulatory Valve	Closed Valve Voiceless	Closed Valve Voiced	Constricted Valve Voiceless	Constricted Valve Voiced	Voiced Nasals
Labiodental (upper teeth and lower lip)			"f"/f/	"v"/v/

labiodental (lower lip to upper teeth); interdental (tongue between the upper and lower teeth); lingual to palate alveolar (tongue to alveolar process of the upper jaw), lingual to palate (tongue to hard palate); and glottal (vocal cords to each other).[124]

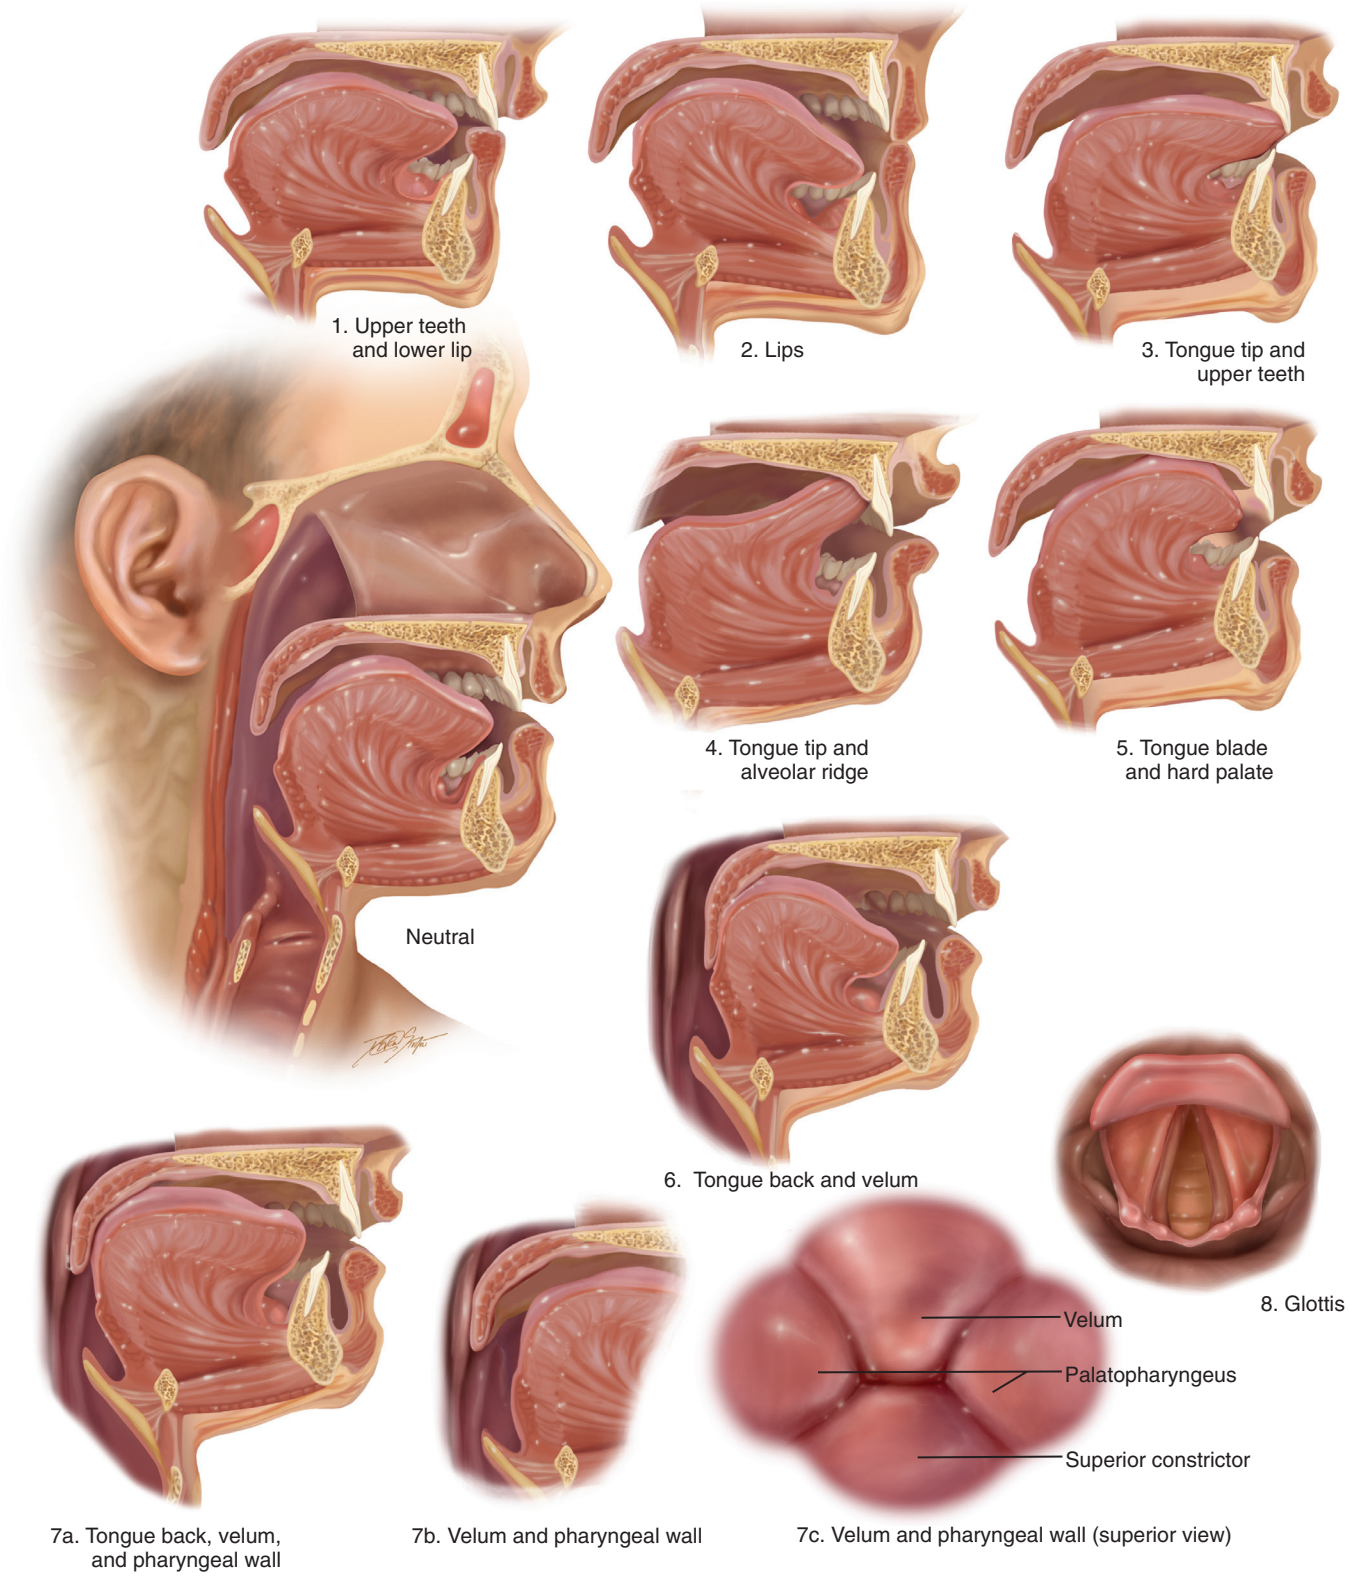
The assessment of speech disorders involves the use of a number of tests and techniques.[23,24,27,32,34,75,109,132,139] Historically, various tests have been described to assess speech and how it compares with recognized normative values. These assessments typically will evaluate sound production in the word position or within sentences. Tests that are frequently used for the assessment of speech are found in Box 8-1.

These tests are based on determining errors when the results are compared with those of normal individuals during single-word utterances. The Bzoch Error Pattern Diagnostic Articulation Test further grades each error type in accordance with its severity. All of these tests fall short for the assessment of the complexities of dynamic speech. Among educators and clinicians, there is often a lack of agreement with regard to a preferred objective method for the analysis of speech. The majority of the published studies were carried out to analyze the effects of orthodontics and orthognathic surgery on speech attempt to document articulation error rates in a traditional manner by noting sound production as simply correct or incorrect and by noting substitutions, distortions, or omissions. Some studies further describe errors as either visual or auditory in an attempt to overcome the usual problems associated with detecting mild sibilant distortions that might not be captured on audiotape.[161]

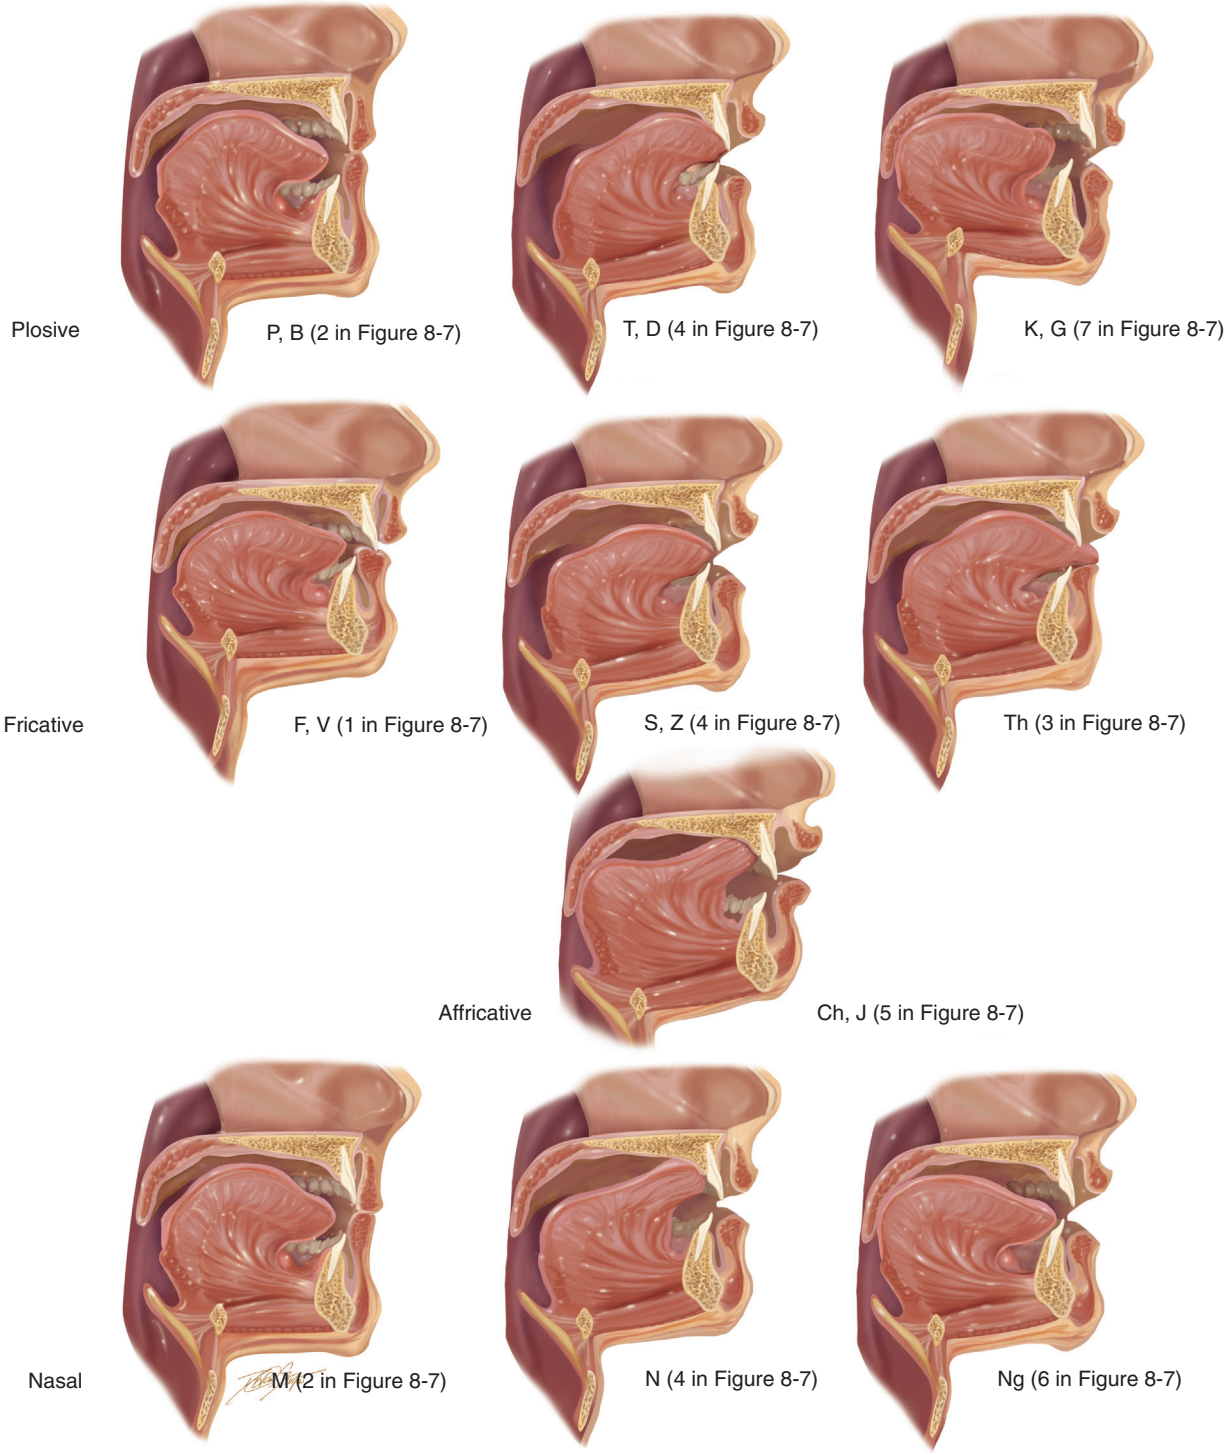
The classic negative effects of a jaw deformity with malocclusion on speech articulation are known.[30,35] The speech benefits of successful orthodontic and surgical correction will have their most notable effects on consonant articulation within the fricative class, which includes /s/, /z/, and /f/. It is known that the /s/ sound in particular is highly sensitive to precise tongue placement and to the accurate direction of airflow across the incisal edges of the upper and lower teeth.

The characterization of speech error type is usually defined as follows:

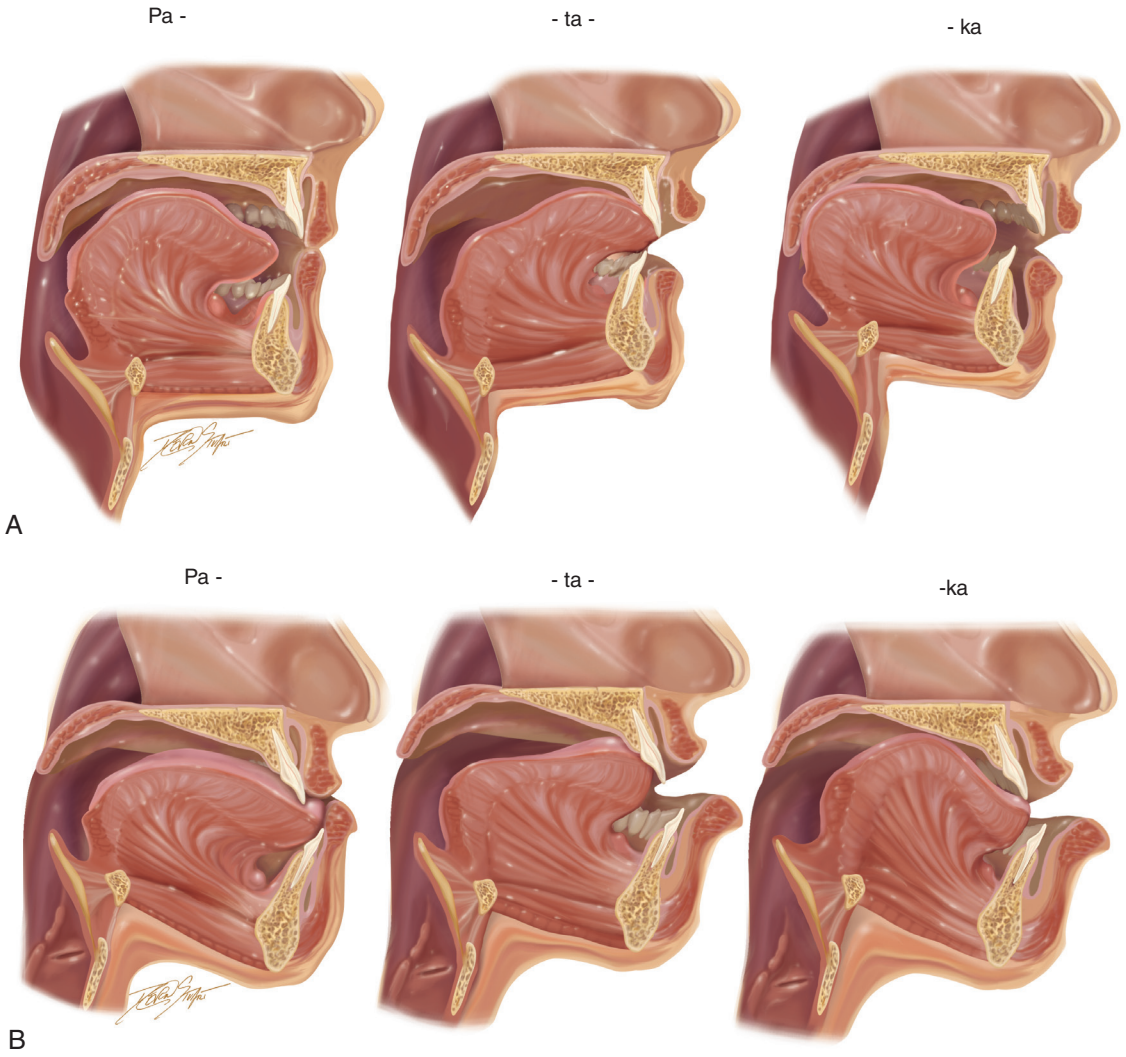
- *Substitution:* when one sound is replaced by another
- *Omission:* when a sound is omitted from a word altogether
- *Distortion:* when sound is not produced appropriately but is still understood
  - *Visual distortion:* when the visual appearance of making the sound is abnormal but the sound itself is correct
  - *Auditory distortion:* when the perception of the sound (what is heard) is abnormal but the appearance (visual appearance) of the positioning of the anatomy is correct



• **Figure 8-7** Diagram showing the kinesiologic positions for the oral and pharyngeal musculature during the articulation of speech sounds.



• **Figure 8-8** Illustrations that demonstrate the articulation of sounds created by specific positions of the lips, tongue, and teeth in the presence of harmonious jaws and occlusion. The numbering allows you to refer back to the chart shown in Figure 8-7, *B*, to correlate the anatomic position of the articulators with the associated speech sounds.



• **Figure 8-9 A,** Drawings that show the representative stages of lip, dental, and tongue positioning during the production of the word *patty-cake.* **B,** In the presence of a jaw deformity with malocclusion, the lips and tongue must position themselves in other locations (i.e., via compensatory mechanisms) to create similar sounds in an attempt to achieve effective communication. This is demonstrated in an individual with a long face Class III negative overjet anterior open-bite malocclusion and similar to what is seen in the patient in Figure 8-11.

- *Combined visual/auditory distortion:* when both the perception of the sound and the appearance of the production of the sound are abnormal

NOTE: Often speech errors become learned rule patterns by individuals on the basis of learned patterns of placement and manners of articulation. After successful orthognathic surgery, relearning may require professional help from a speech pathologist.

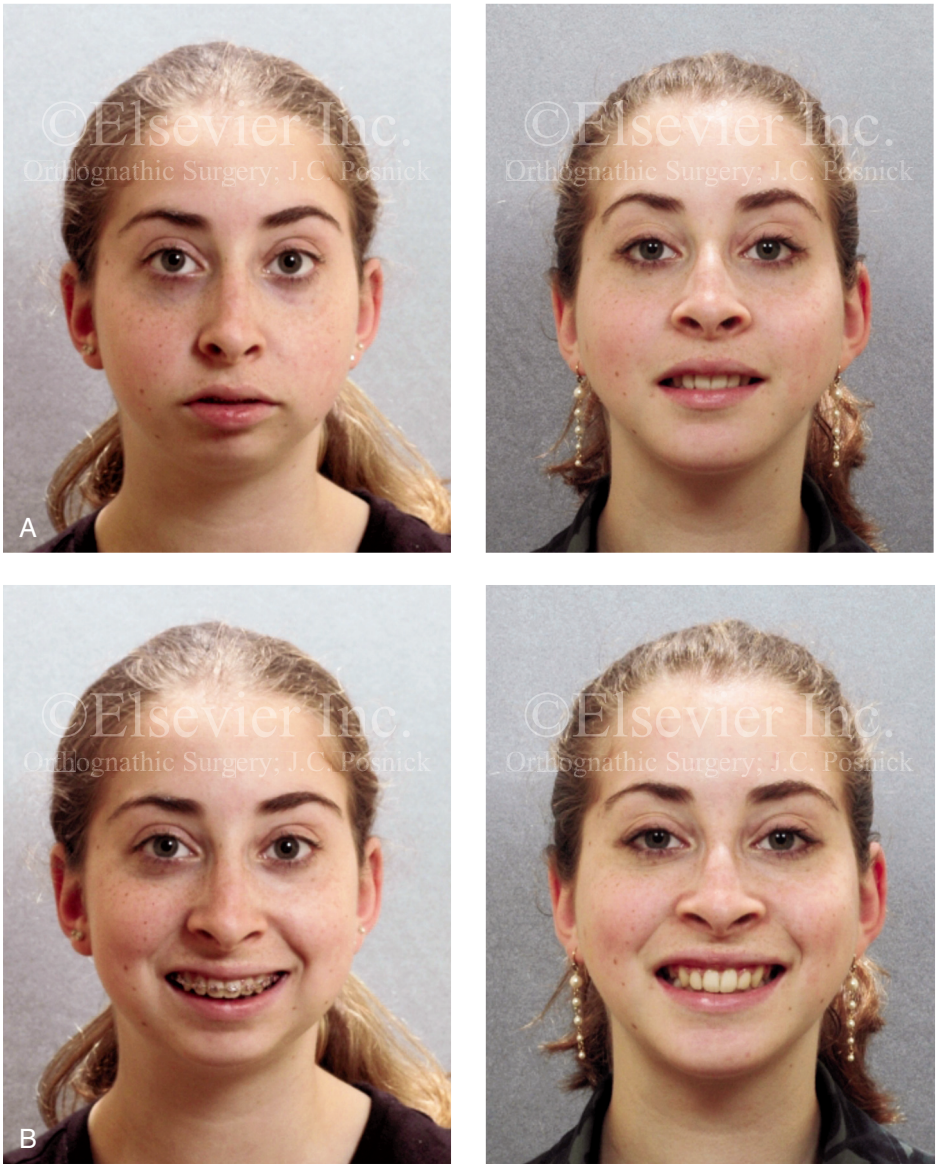
Effects of Jaw Deformities with Malocclusion on Speech

Background

Published studies show a tendency for individuals with Angle Class I occlusions to rate better with regard to speech as compared with those individuals with malocclusions.[37] A review of the literature shows a significant association between misarticulation in speech and Angle Class II malocclusion (Fig. 8-10), Angle Class III malocclusion (Fig. 8-11), and anterior open-bite malocclusion (Fig. 8-12).[39,43,53,54] Studies that evaluate speech articulation in individuals with jaw deformity and malocclusion confirm that as many as 90% of affected individuals have significant misarticulation errors. Several published studies report articulation errors among all jaw deformity patients analyzed.[39,47,53]

The jaw deformity patterns that are most frequently associated with significant articulation errors include those with 1) Angle Class II open-bite malocclusion in association with vertical maxillary excess and mandibular deficiency (i.e., the long face growth pattern; see Chapter 21) and 2) Angle Class III negative overjet malocclusion in association with maxillary deficiency and relative mandibular excess (see

Text continued on p. 252



• **Figure 8-10** A 16-year-old girl arrived with her parents for the surgical evaluation of a developmental jaw deformity with malocclusion. She was diagnosed with a primary mandibular deficiency, a maxillary arch constriction, and a Class II excess overjet growth pattern. Attempts at orthodontic growth modification and camouflage in the past were unsuccessful. There was a lifelong history of obstructed nasal breathing, heavy snoring, and the suggestion of sleep apnea. The patient experienced difficulty with chewing, swallowing, speech articulation, breathing, and lip closure/posture. A formal evaluation by a speech–language pathologist was carried out.

Chewing/swallowing:

- Difficulty with chewing solid, textured food
- Only able to chew on the back teeth
- Frequently swallows foods partially whole, especially raw vegetables and meat

Oral-sensory motor:

- Normal to mild labial weakness during repeated puckering and retraction tasks
- Lingual range of motion within normal limits
- Palatal structures revealed adequate elevation

Articulation:

- Assessed via the Fisher-Logemann Test of Articulation and informally during speech and conversation
- Misarticulations were identified, including /s/, /sh/, /st/, /z/, /dz/, and /sk/

Continued

• **Figure 8-10, cont'd**

Production of sounds:

- Anterior tongue thrusting is required to facilitate speech sounds in conversation and in contextual speech.
- Imprecision in speech makes her difficult to understand.
- She frequently uses a closed-mouth posture to speak, thereby causing her speech to be unintelligible for the listener.

Recommendations:

The patient's presenting jaw deformity and malocclusion interfere with her ability to communicate information precisely to a listener and to be understood. Orthodontic treatment and orthognathic surgery are recommended to correct the maxillofacial deformities. If successful, then improvements in the dysfunctions described should be expected. It is highly doubtful that speech therapy alone could solve the extent of the deficits.

Treatment

The patient agreed to a combined orthodontic and surgical approach. Mandibular first bicuspid extractions provided space to orthodontically relieve dental compensation. Surgery included a maxillary Le Fort I osteotomy (arch expansion and horizontal advancement); bilateral sagittal split ramus osteotomies (horizontal advancement); osseous genioplasty (horizontal advancement); and septoplasty and inferior turbinate reduction.

• **Figure 8-11** An 18-year-old man arrived with his parents for the surgical evaluation of a developmental jaw deformity with malocclusion. He was diagnosed with a long face Class III anterior open-bite negative overjet growth pattern. This was due to both a hereditary Class III tendency and a lifelong obstructed nasal breathing open-mouth posture. The patient described difficulty with chewing, swallowing, speech articulation, breathing, and lip closure/posture. A formal speech–language pathologist's evaluation was carried out.

Chewing/swallowing:

- Frequent need to tear food apart before chewing
- Unable to bite into solid, textured food
- Only able to chew on the posterior teeth
- Frequently noted to swallow foods partially whole
- Difficulty with eating meats and breads

Oral-sensory motor:

- Labial motion and strength greatly reduced, especially with puckering and retraction of the tongue
- Soft palate structure and elevation within normal limits

Articulation:

- Assessed via the Fisher-Logemann Test of Articulation and informally during spontaneous conversation
- Misarticulations were identified, including /s/, /sh/, /z/, /dz/, /sk/, /ch/, and /s/ blends

Continued

• **Figure 8-11, cont'd**

Production of sounds:

- Production of sounds required anterior tongue thrusting and lateral lisping
- Exhibited imprecision in coarticulation, which often interfered with speech intelligibility
- Speech rate is rapid, with mumbling used as a compensatory feature for communication
- Frequently uses closed-mouth posturing with lack of enunciation, which greatly interfere with communication
- States that friends, teachers, and parents often comment that they cannot understand his speech
- Unintelligible speech interferes with daily performance at school and in social situations
- Avoids telephone conversations and hesitates to leave voice messages as a method of communicating

Recommendations:

The presenting jaw anomalies and malocclusion are responsible for the described findings. Orthodontics and orthognathic surgery are recommended to correct the maxillofacial anatomy. If successful, it is highly probable that the dysfunction described will resolve.

Treatment

The patient agreed to a combined orthodontic and surgical approach. With the removal of dental compensation, surgical procedures included a maxillary Le Fort I osteotomy (arch expansion, arch form correction, horizontal advancement, clockwise rotation, and vertical shortening); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring.

A, Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment. **C,** Oblique facial views before and after treatment. **D,** Profile views before and after treatment.

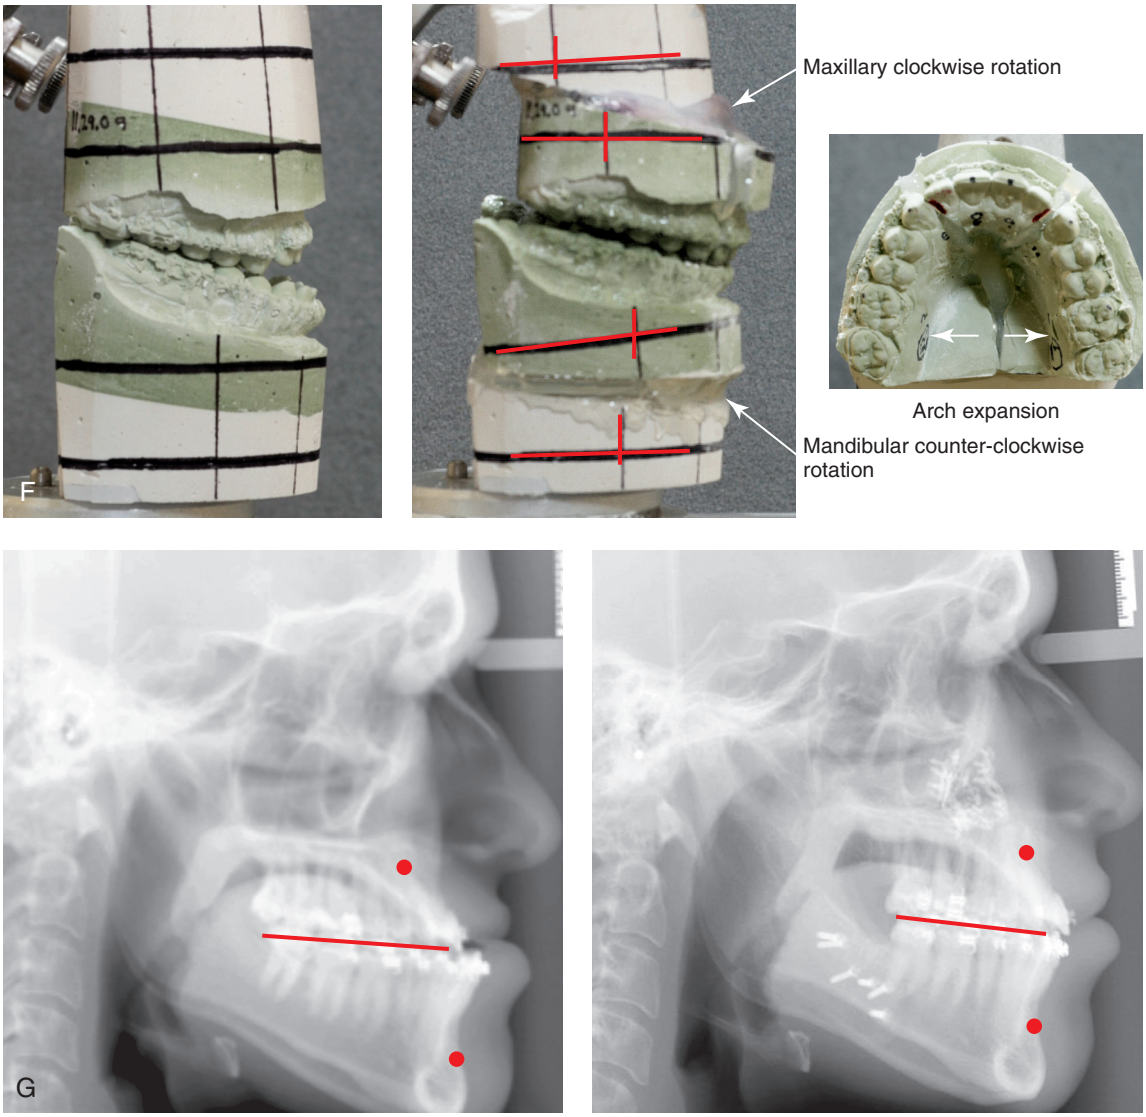
Prior to treatment

Pre surgery

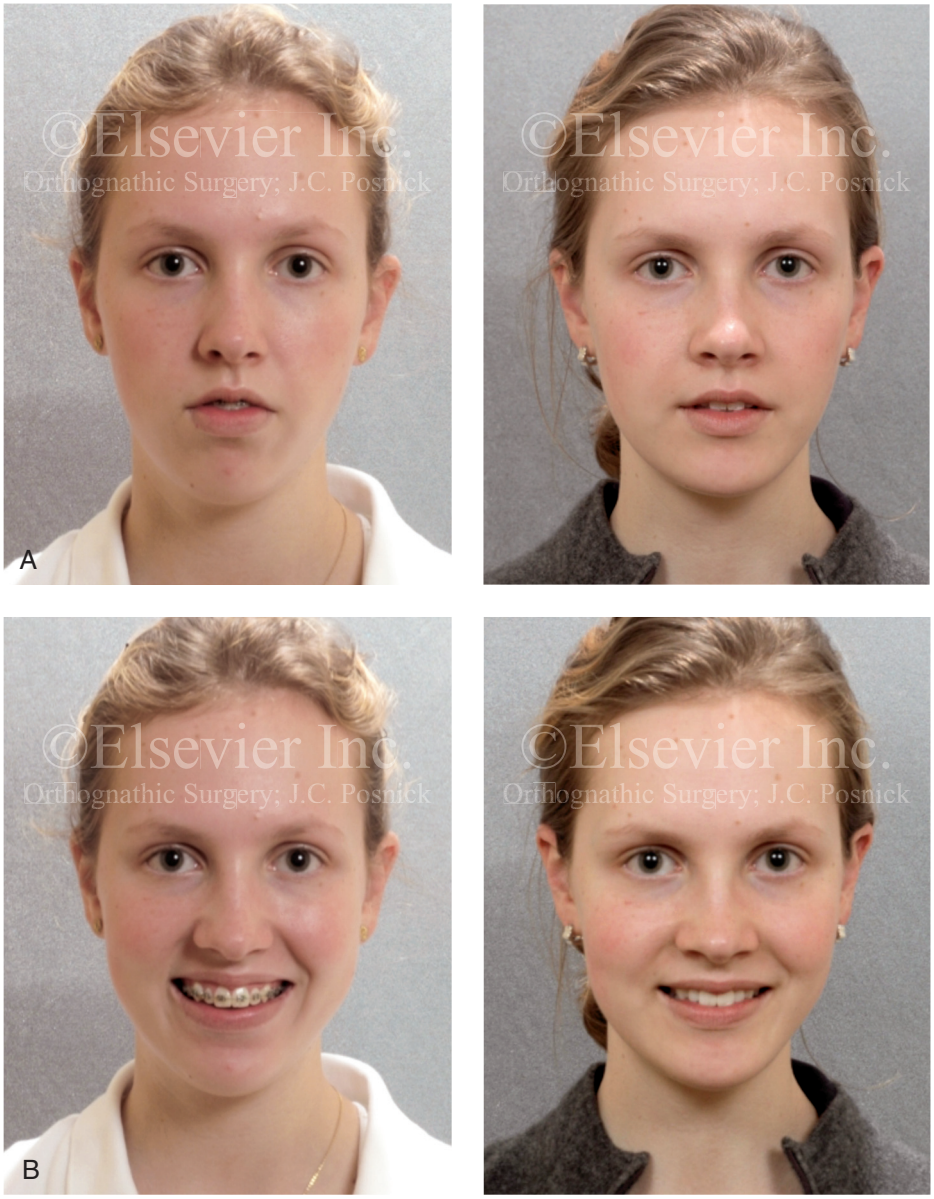
After treatment

• **Figure 8-11, cont'd E,** Occlusal views before treatment, with orthodontics in progress, and after treatment.

Continued



• **Figure 8-11, cont'd** **F,** Articulated dental casts that indicate analytic model planning. **G,** Lateral cephalometric radiographs before and after treatment.



• **Figure 8-12** A 16-year-old girl arrived with her parents for the evaluation of a developmental jaw deformity with malocclusion. She was diagnosed with a long face Class II anterior open-bite growth pattern. She had undergone years of orthodontic growth modification and camouflage treatment, without success. Her dentofacial deformity was found to affect speech, chewing, swallowing, breathing, and lip closure/posture. A formal speech–language pathologist's evaluation was carried out.

Chewing/swallowing:

- Only able to chew on the posterior teeth
- Malocclusion results in frequently swallowing food whole
- Noted to frequently have food falling out of her mouth secondary to malocclusion

Oral-sensory motor:

- Mild labial weakness
- Demonstrates anterior carriage of the tongue at rest
- Tends to hold oral cavity in a closed posture during speech

Articulation:

- Assessed via the Fisher-Logemann Test of Articulation and informally during conversation
- Misarticulations were identified, including /s/, /sh/, /z/, /dz/, /z/, /sk/, and /st/

Continued

• Figure 8-12, cont'd

Production of sounds:

- Sound production is with anterior tongue thrusting and lateral lisping during contextual speech
- Exhibits imprecise coarticulation, which interferes with speech intelligibility
- Speech rate is often fast, which compounds the difficulties with articulatory precision (i.e., perceived mumbling)
- Occasional final consonant deletions were noted

Recommendations:

The correction of the presenting abnormal jaw morphology and dental malposition is recommended, if feasible, through orthodontics and orthognathic surgery.

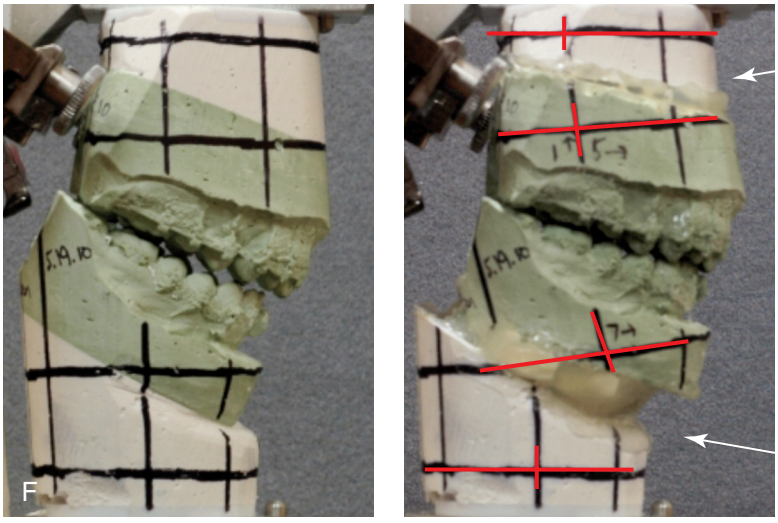
Treatment

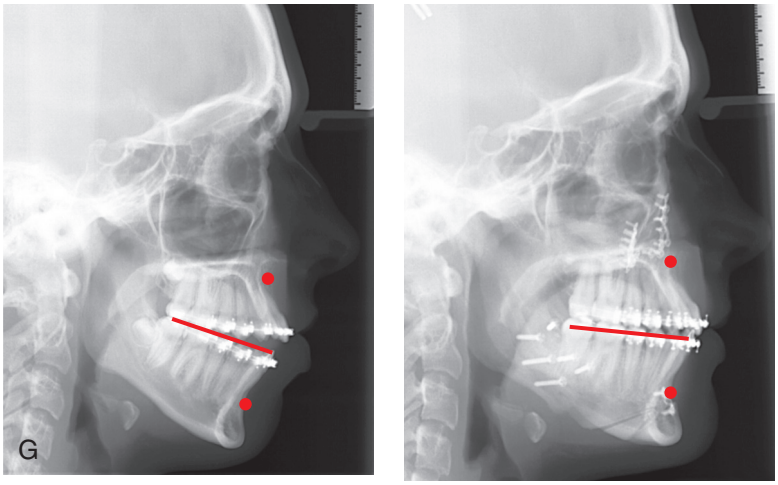
Further orthodontic (dental) decompensation in combination with orthognathic surgery was planned. The procedures included a maxillary Le Fort I osteotomy (vertical intrusion, horizontal advancement, and counterclockwise rotation); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical shortening and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring.

A, Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment. **C,** Oblique facial views before and after treatment. **D,** Profile views before and after treatment.

Pre surgery

After treatment





• **Figure 8-12, cont'd** **E,** Occlusal views before surgery and then after treatment. **F,** Articulated dental casts that indicate analytic model planning. **G,** Lateral cephalometric radiographs before and after surgery.

Chapter 20).[46,61,157] There were less articulation errors found in patients with Angle Class II primary mandibular deficiency malocclusions (see Chapter 19) and in patients with conditions that involve jaw asymmetry without significant malocclusion (i.e., mild hemifacial microsomia; see Chapter 28).[67] Voice disorders were more frequently seen with closed-bite malocclusion as compared with open-bite malocclusion. Closed-bite jaw deformities are generally associated with adequate overjet and often with a deep overbite (i.e., the short face growth pattern; see Chapter 23).[50]

Patients with Class III skeletal patterns show distinct differences with regard to the consonant fricatives (/f/ and /s/) as compared with normal controls.[73] Distortion type speech errors are also frequently associated with this type of malocclusion. This is especially true for patients with combined acoustic and visual errors. The speech sounds that are most commonly affected in the presence of malocclusion are sibilant sounds and bilabial (i.e., upper lip to lower lip) sounds. Errors in bilabial sounds are generally found in individuals with wide lip separation, such as those with maxillary deficiency in combination with mandibular excess or long face growth patterns (i.e., vertical maxillary excess and mandibular deficiency).[87]

Class II mandibular retrusion with excess overjet is likely to produce significant bilabial errors (see Fig. 8-10). Patients with Class II mandibular retrognathia also frequently show misarticulation errors (e.g., with the sound /r/). It is known that individuals with mild to moderate Class II mandibular retrusion are frequently able to adapt by posturing their lower jaw forward (i.e., by having a dual bite) to maintain control of their speech. This compensatory jaw position mechanism tends to break down with rapid speech or when the individual is otherwise fatigued.[130] As a result of the inherent anatomic barriers, it is not possible for patients with maxillary deficiencies or mandibular excesses with significant negative overjet to posture their lower jaw posteriorly as a method of speech compensation (see Fig. 8-11).[147] This makes the production of the /s/ sound difficult for most individuals with Class III malocclusions.[133]

Published reports indicate that, for a majority of the individuals studied, the orthodontic and surgical correction of the baseline jaw deformity and malocclusion either eliminates or dramatically reduces articulation errors.[95,97,106,107,113,127,146] A minority of the study patients report little change and occasionally speech deterioration. This lack of success in some patients is most likely attributable to 1) initial errors in dental or jaw diagnosis; 2) the incomplete initial correction of the dental or jaw deformity 3) or long-term skeletal or dental relapse with a return of the abnormal dental or jaw position. The inability of an individual with normal neuromotor ability to favorably adapt to the corrected dental and jaw relationships is not the most common reason for a lack of speech improvement. Nevertheless, some individuals will be in need of speech articulation retraining after corrective surgery and orthodontics.

Unfortunately, many of the published studies that set out to evaluate speech aspects after the orthodontic and surgical correction of the initial jaw deformity or malocclusion include too few subjects, have inadequate controls, mix varied patterns of dental and jaw deformities, and lack a standardization of the sampling times before and after treatment.* Some of the published studies seem to lack an understanding of the expected postoperative convalescence, during which short-term speech disability is to be expected. Definitive speech evaluation should occur after adequate healing (i.e., 3 to 6 months) and with documentation of the level of success of the correction of the jaw deformity and malocclusion. As a result of these study shortcomings, there is a need for the further investigation of the speech effects of jaw and dental corrections with 1) larger samples of homogenous patterns of jaw deformity and malocclusion 2) standardized treatment protocols 3) the confirmation of the actual correction of jaw dysmorphology and malocclusion 4) the setting of agreed-upon speech sampling parameters 5) interobserver and intraobserver error testing of speech evaluations and 6) appropriate statistical analysis.

Cause and Effect Relationships

If the upper and lower lips cannot easily close together—as is frequently observed in patients with Angle Class III negative overjet skeletal patterns (e.g., maxillary deficiency with relative mandibular excess; see Fig. 8-11) or in those with classic long face growth patterns with Class II anterior open-bite malocclusion (e.g., maxillary vertical excess with mandibular deficiency; see Fig. 8-12)—then bilabial sounds (e.g., words such as *pill, baby,* and *man*) cannot be normally formed.[55,95,97,104,136] These sounds will then be attempted through labiodental articulation. If the lower lip cannot contact the upper incisors (e.g., long face growth pattern with Class II anterior open-bite malocclusion or maxillary deficiency with mandibular excess negative overjet), then labiodental sounds (e.g., words such as *five* and *vein*) will be affected. Compensation will be attempted with bilabial sounds. If the tongue has difficulty reaching the lingual alveolar ridge of the maxilla (e.g., with moderate to severe Class II mandibular retrognathia), if the airstream cannot be correctly directed to the edges of the incisors (e.g., with an anterior open bite), or if the tongue is too far from the anterior aspect of the lower jaw (e.g., with Class III mandibular excess), then sibilant sounds (e.g., words such as *sun, zoo, ship, chair, judge,* and *measure*) will be affected (see Fig. 8-10).

Interestingly, from a speech perspective, some individuals are able to adapt to their dental or jaw defects more effectively than others. The individual's ability to alter the airflow over the incisors or through other articulation points is necessary to effectively compensate for anatomic

*References 8, 21, 18, 28, 29, 40, 42, 44, 45, 74, 106, 113, 126, 127, 131, 134, 135, 137, 146, 148, 150

variations in the teeth and jaws. Marked deformities such as severe Class III maxillary deficiency (see Fig. 8-11), severe long face growth pattern (i.e., anterior open bite with mentalis strain; see Fig. 8-12), and severe Class II mandibular retrognathia with the inability to posture the jaw forward (see Fig. 8-10) are examples of situations in which compensation is not possible and speech articulation is noticeably affected. With successful orthodontics and jaw surgery, improved positioning of the teeth, jaws, lips, tongue, and soft palate results in ease of articulation to accomplish effective speech.[28,74,126,131,137]

It is not surprising that vowel sounds are less frequently disturbed by a jaw disproportion or malocclusion. Physiologically, the major difference between vowel sounds and consonant sounds is that consonant sounds require significant constriction of the airflow within the vocal tract, whereas vowel sounds are formed by the tongue being positioned to only partially constrict the airflow.[143] Therefore, *consonant sounds* are more dependent on an exact positioning of the teeth with respect to each other and the lips with respect to each other (i.e., complete valve closure). Consonant sounds are more affected by jaw deformities such as Class III maxillary deficiency; long face anterior open bite; and severe Class II mandibular retrusion. These abnormal skeletal and occlusal patterns significantly interfere with the production of speech sounds. However, each individual's speech system has variable adaptive ability. The adaptability primarily comes from the stretching of the lips (i.e., mentalis strain); the stretching of the tongue to extended positions; the posturing of the lower jaw forward (i.e., centric relation to the centric occlusal slide); and the ability to alter the airflow force across the valves and sphincters. The ability of an individual to control these factors is also dependent on the speed of speech and the amount and length of continuous speech required.

Effects of Successful Orthodontics and Orthognathic Surgery on Speech

Effects on Speech Articulation: Review of the Literature

A study by **Witzel and colleagues** examined the articulation of 41 individuals before and after orthognathic surgery that was carried out to improve facial aesthetics and to correct the occlusion.[150] The investigators found a direct relationship between the pretreatment degree of mandibular retrognathia and the confirmed speech articulation errors. Twenty-two of 29 (76%) of the study patients had documented articulation errors before surgery; these included errors in sibilant production, labiodental sounds, and bilabial sounds. After surgery, significant improvement in the mean total articulation score for each patient was documented. There was also significant improvement in the sibilant sounds for all groups and in the mean bilabial scores of patients with mandibular retrognathia. Individuals with a Class III skeletal pattern and significant negative overjet (e.g., maxillary deficiency with relative mandibular excess) achieved the maximum improvement in labiodental scores after successful orthodontic and surgical correction.

Ruscello and colleagues studied the speech characteristics of 20 individuals who were scheduled to undergo orthognathic surgery for the correction of a variety of dentofacial deformities.[106,107] They underwent speech evaluation before and at intervals for up to 6 months after surgery. Speech assessment at each interval included the Templin-Darley Screening Test of Articulation, a 60-item nonsense syllable task, the Deep Test of Articulation, and the Rainbow Passage. Sixty percent of the patients with jaw deformities demonstrated preoperative articulation errors. The majority of those who were exhibiting preoperative articulation errors had documented improvements after surgery. None of the patients experienced a deterioration in their articulation after surgery at the close of the study.

Kummer and colleagues studied 16 skeletal Class III patients before and after Le Fort I maxillary advancement.[71] Seven of the 16 study patients were adolescents with repaired cleft lip and palate. Each patient underwent preoperative and postoperative speech evaluations and a multi-view videofluoroscopic speech study. Patients were evaluated before surgery as well as 3 and 6 months after surgery. The Templin-Darley Screening Test of Articulation was given, and articulation, resonance, and nasal emission were judged at each time interval. Eleven of 16 patients (69%) demonstrated articulation errors before surgery. After surgery, 7 of these 11 (64%) patients (4 without clefts and 3 with clefts) showed a decrease in the number of misarticulation speech sounds. None of the patients showed deteriorations in articulation after surgery.

Vallino studied the articulation, voice, resonance, hearing sensitivity, and middle-ear function of 34 individuals before and at intervals (i.e., at 3, 6, 9, and 12 months) after they underwent orthognathic surgery.[129] Thirty of the 34 patients (88%) exhibited articulation errors before surgery. The most frequent sibilant errors were /s/ and /z/, followed by /j/, /zh/, /ch/, and /sh/. The errors were predominantly distortions of both the visual and acoustic types. After surgery, articulation generally improved spontaneously, without the need for speech training or intervention. Most of the preoperative articulation errors were eliminated by 3 months after surgery. In a minority of the study patients, a gradual decline in some of these improvements was measured at 12 months after surgery. This could be explained by either a relapse of the initial satisfactory occlusion and jaw correction or a limited sustained adaptation of speech ability in some individuals. Interestingly, voice, resonance, and hearing sensitivity were not altered by the surgeries that were carried out.

Xue and colleagues carried out a study to compare vocal tract configuration in males with skeletal Class III malocclusion (n = 8) with that of their normally developed Class I counterparts (n = 8).[157] The goal of these researchers was to investigate the concomitant acoustic changes caused by any alterations in the vocal tract configuration that were

identified. The findings of the study confirmed that young adolescents with Class III malocclusion had different vocal tract configurations than their counterparts with normal occlusion. The differences occurred in the oral cavity only. The individuals with Class III malocclusion had significantly longer oral length and larger oral volume than their counterparts in the control group. They surmised that the Class III dentofacial deformity restricted lip protrusion during the production of /u/, thereby contributing to the significantly higher resonating frequency (first formant or F1) of /u/ as compared with that of normal controls.

A review of these studies indicate that a majority of individuals who present with moderate or severe jaw deformity and malocclusion will demonstrate articulation errors during speech. The pattern of jaw deformity (i.e., Class II, Class III, open bite, or long face) will predict the pattern of specific articulation errors. Some individuals will have a greater ability to adapt to their dentofacial deformity to achieve relatively normal articulation.

Distortions are the most frequently reported errors, which occur in association with malpositioning of the jaws and teeth. They are of more concern than substitutions or omissions. Individuals will attempt to adapt, but their speech production will not always be within acceptable phonetic boundaries. The most frequent speech sound errors are of the /s/ speech sounds, which are sibilants produced in the alveolar part of the palate with the tongue resting in this region. This type of sibilant distortion error can occur with a spectrum of jaw deformities (e.g., mandibular retrognathic Class II).

NOTE: Residual misarticulations may become learned behavior patterns. If this occurs, a few speech treatment sessions may be required for complete correction during contextural speech production. We have found that adults more frequently than adolescents benefit from speech therapy sessions after successful surgery and orthodontics.

In general, individuals who present with articulation errors caused by dentofacial deformity with malocclusion are expected to achieve improved speech function after successful jaw surgery and orthodontics. This assumes that the individual articulators are placed in sufficient proximity to each other. Published studies indicate that 80% to 90% of individuals will find positive improvement in their articulation after the vocal organs are correctly positioned. Interestingly, approximately 10% of individuals are found to be either unchanged or to show some negative effects in speech articulation after jaw surgery. Possible explanations for this small failure rate include errors in jaw or dental diagnoses; unsatisfactory surgical or dental execution; skeletal or dental relapse; effects of neurosensory deterioration; or the inability of the individual to adapt over the long term.

Effects on Velopharyngeal Function: Review of the Literature

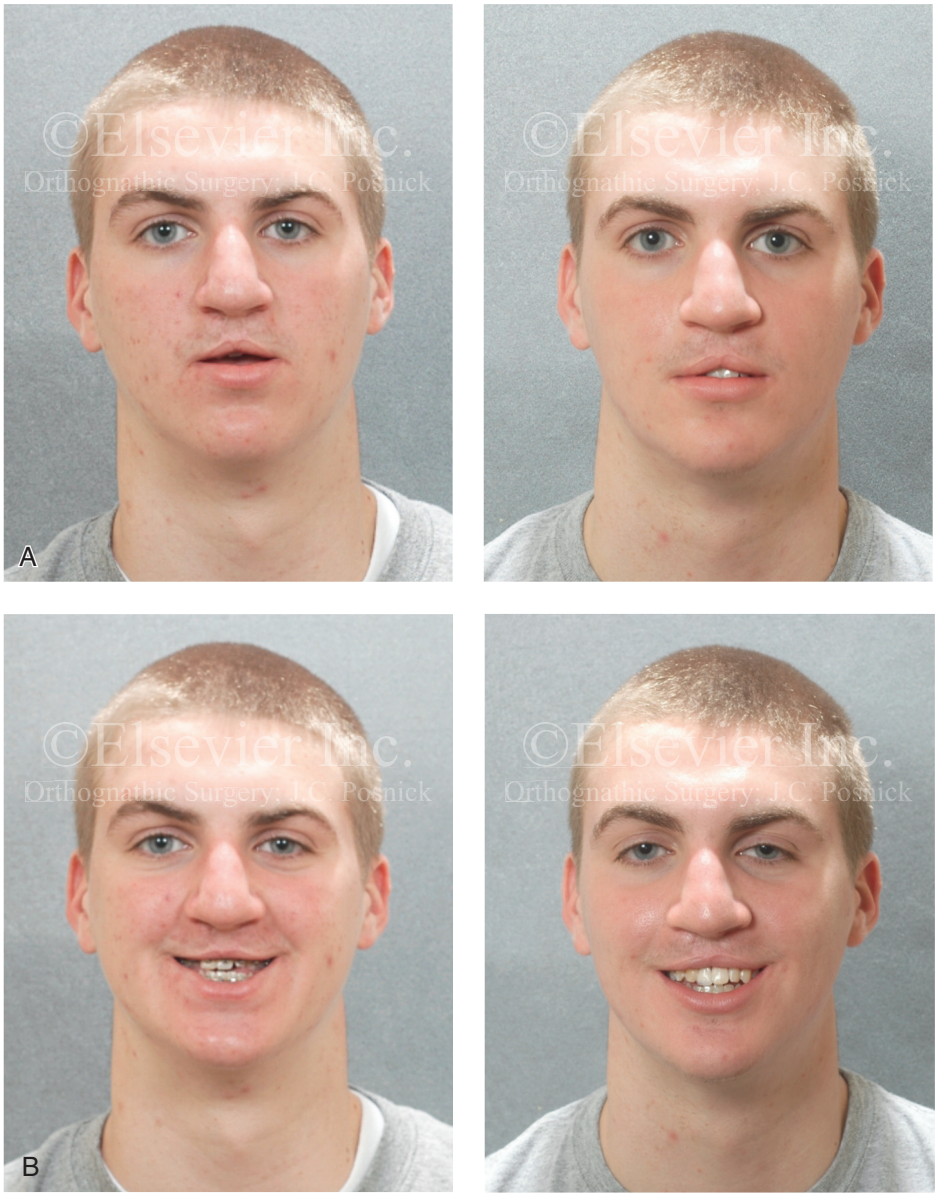
Velopharyngeal insufficiency (VPI) is the hallmark sign of the negative speech effects among individuals who are born with cleft palates.[7,12,22,52,76,91] The basic etiology of VPI in the repaired or unrepaired cleft palate is dysfunction of the soft palate (Fig. 8-13).[13,19,20,51,101,111] The muscular anatomy that is affected by clefting includes both the elevators of the soft palate (i.e., the musculus uvulus and the levator veli palatini) and the antagonists to the elevators (i.e., the palatoglossus and the palatopharyngeus).[56,69,70,116-118,145,160] VPI involves the inadequate closure of the velum to the pharyngeal walls while speaking.[78,108,141,142] VPI results in increased nasal air escape with increased nasal resonance that can be heard.[72,88,159] Resonance disorders include both hypernasality and hyponasality.[77] When there is improper control of airflow across the velopharyngeal (VP) sphincter, hypernasality can occur, with increased nasal resonance occurring during the production of vowel sounds.[84,153,154] Hyponasality is defined as a reduction in normal nasal resonance as a result of the blockage of airflow within the nasal cavity.[92,104] A review of the literature is helpful to better understand the effects of Le Fort I osteotomy with advancement on VP function.*

In 1969, **Jabaley and Edgerton** were the first to report about the potential for changes in the spatial relationship of the soft palate to the pharyngeal wall as a result of maxillary Le Fort I advancement.[63] They described an 18-year-old patient without clefting who underwent a Le Fort I osteotomy with advancement. They stated that there was "no adverse alteration of velopharyngeal function accompanying the maxillary advancement."[63]

In 1976, **Schwarz and Gruner** reported about 40 patients who were undergoing Le Fort I osteotomy with repositioning (31 out of 40 with repaired cleft palate).[113] The authors concluded that the "subjective evaluation of velopharyngeal function and nasality in the cleft palate patients showed no relationship between the degree of hypernasality before or after the Le Fort I advancement."[113]

Witzel and Munro discussed a 16-year-old patient with a repaired unilateral cleft lip and palate who presented to them with maxillary hypoplasia and malocclusion.[149] Before surgery, this patient's VP valving mechanism showed only touch closure of the soft palate against the posterior pharyngeal wall. Two months after Le Fort I osteotomy (10 mm of advancement and 4 mm of vertical lengthening), his speech evaluation revealed marked hypernasality throughout connected discourse. The authors concluded that "maxillary advancement may have a disastrous effect on the velopharyngeal valving mechanism."[149] They recommended that "all patients undergoing this procedure should have detailed clinical investigation of speech and velopharyngeal function pre- and postoperatively."[149]

*References 9, 14, 15, 38, 45, 47-49, 64, 68, 71, 82, 83, 85, 98, 102, 110, 125, 128, 129, 144, 149, 152, 155



• **Figure 8-13** A 15-year-old boy was born with bilateral cleft lip and palate. Previous cleft surgery included bilateral cleft lip repair (3 months of age); cleft palate repair (12 months of age); and alveolar bone grafting (8 years of age). The patient has maxillary deficiency and secondary deformities of the mandible, and there is chronic nasal obstruction (i.e., septal deviation, inferior turbinate hypertrophy, and nasal floor irregularities). There is a severe Class III negative overjet malocclusion. Orthodontic (dental) decompensation has been carried out in preparation for jaw and intranasal surgery. The patient's current maxillofacial findings affect speech, chewing, swallowing, breathing, and lip closure/posture. A formal speech–language pathologist's evaluation was carried out.

Chewing/swallowing:

- Able to chew on posterior teeth only
- Occasional nasopharyngeal leakage (into the nose) when drinking milk

Oral-sensory motor:

- Maxillary hypoplasia with Class III malocclusion
- Exhibits mild lip weakness with protrusion and retraction
- Lingual movements appear adequate
- Ability to elevate the soft palate is suspect

Articulation:

- Assessed via the Fisher-Logemann Test of Articulation and during informal conversation
- Misarticulations were identified, including /s/, /sh/, /z/, /dz/, /sk/, and /st/

Production of sounds:

- Sibilant sounds were noted to involve anterior tongue thrusting and lateral lisping during contextual speech
- Exhibits imprecision in coarticulation of speech, which interferes with speech intelligibility
- Unintelligible speech is frequently noted, with mumbling

Continued

• **Figure 8-13, cont'd**

Nasopharyngeal examination:

- Nasal emission under right nares observed during non-nasal speech sounds
- Soft palate motion weak
- Shortened palate during non-nasal speech production of phrases and single words
- Good lateral wall movements bilaterally

Recommendations:

- Exhibits sound misarticulations associated with jaw anomaly and malocclusion
- Misarticulations affect speech function during routine conversation
- Forced to use anterior tongue thrusting and lateral lisping, which distort speech and affect perception of intelligence
- Rated as having inadequate velopharyngeal closure before jaw reconstruction
- Reassess 3 to 6 months after jaw surgery, with anticipated need for a pharyngeal flap

Treatment

Further orthodontic (dental) decompensation in combination with orthognathic surgery was planned. The procedures included maxillary Le Fort I osteotomy (vertical intrusion, horizontal advancement, and counterclockwise rotation); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical shortening and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring.

Six months after successful jaw and intranasal reconstruction; a nasoendoscopic speech assessment confirmed the need for a tailor-designed pharyngeal flap.

Epker and Wolford observed that adolescent patients with repaired clefts, maxillary deficiency, and preoperative VPI became worse after Le Fort I advancement.[29] The authors stated that individuals with only borderline VP closure may demonstrate notable VPI after maxillary osteotomy, particularly if the advancement exceeds 10 mm. **Bralley and Schoeny** reported about a 19-year-old patient with a submucous cleft palate and maxillary deficiency who showed no change in nasality after Le Fort I advancement.[9] Schendel and colleagues evaluated 21 patients without clefts before and after maxillary Le Fort I osteotomy to assess VP closure.[110] They did this through speech evaluation, lateral cephalometric radiography, and nasopharyngoscopy, and they found no change in VP competence after Le Fort I advancement.

Witzel described a sample of 41 patients without cleft palate and 50 patients with repaired cleft palate (bilateral, unilateral, or isolated) who underwent Le Fort I maxillary advancement.[152] The results indicated that patients without cleft palate have a very low risk of deterioration of VP function. Patients with a repaired cleft palate who had adequate VP function before Le Fort I advancement were also at lower risk. However, 11 of 15 of the study patients with a repaired cleft palate and a preoperative rating of borderline VP closure acquired surgically induced symptomatic VPI after Le Fort I advancement. Patients who were considered to have inadequate VP closure before surgery remained so after surgery. For most patients, the extent of preoperative competence of the VP sphincter before Le Fort I advancement predicted the competence of the VP sphincter after surgery (as documented by videofluoroscopy and nasoendoscopy).

Kummer and colleagues reported on VP function in two different patient groups: those with repaired clefts and those without clefts who underwent maxillary Le Fort I advancement with or without vertical change.[71] The measured change in VP function was not clinically significant. They concluded that "Le Fort I maxillary osteotomy has a negligible effect on velopharyngeal function in both cleft and non-cleft cases."[71]

Vallino discussed 34 patients without clefts before and at intervals after orthognathic surgery that included Le Fort I osteotomy.[129] The VP port area was measured in the study patients before and at intervals (i.e., 3, 6, 9, and 12 months) after Le Fort I osteotomy. The estimation of the size of the VP port area was obtained with the pressure-flow technique

described by Warren and Dubois.[139] All study patients demonstrated VP port areas that measured between 0 and 0.49 cm^2 both before and after surgery across all speech tasks, which indicated adequate VP competence. The author concluded that the Le Fort I osteotomies carried out in patients without clefts did not alter the VP valve or cause hypernasal speech.

Watzke and colleagues evaluated VP function with the use of aerodynamic testing before and at least 1 year after Le Fort I maxillary advancement in 24 adolescents with repaired cleft palates.[144] Five of these patients (23%) demonstrated VP deterioration, whereas another five (23%) showed improvement after Le Fort I advancement. Interestingly, those patients with a pharyngeal flap in place had a higher incidence of improved VP function after surgery. Of the five (23%) that showed VP deterioration, four had adequate VP function and one had borderline VP function preoperatively. Fourteen (46%) of the patients with clefts showed no significant change in VP function as a result of Le Fort I advancement.

Janulewicz and colleagues completed a retrospective study that evaluated VP function in patients with repaired cleft lips and palates (N = 54) who underwent maxillary Le Fort I advancement.[64] The authors documented a significant deterioration of VP function in many of the patients with clefts after Le Fort I advancement. There was also an increase in hypernasality, which further supported the findings of VP deterioration in a subgroup of the patients with repaired clefts after Le Fort I advancement. The authors also found improvements in hyponasality as compared with in preoperative values, which was attributed to a decrease in nasal airflow obstruction after maxillary advancement.

Velopharyngeal Evaluation Among Individuals with Repaired Cleft Palates and Maxillary Deficiencies Undergoing Le Fort I Advancement

A variety of methods for the assessment of VP function have been described.[57,62,86,89,90,93,94,99,100,105,115,119,140,152] A protocol for the evaluation of patients undergoing orthognathic surgery has been advanced by the American Cleft Palate-Craniofacial Association in *Parameters for Evaluation and Treatment of Patients with Cleft Lip/Palate or Other Craniofacial Anomalies* (American Cleft Palate-Craniofacial Association, Revised edition 2009 www.acpa-cpf.org).

Witzel also developed a protocol for the evaluation of VP function in adolescents and adults after palate repair to anticipate alterations in the VP sphincter after maxillary Le Fort I osteotomy.[154] She recommends a routine speech assessment that includes instrumentation evaluation of VP function, preferably with nasoendoscopy or, as a second choice, videofluoroscopy. After surgery and sufficient time for healing (i.e., 6 to 12 months), a final assessment of articulation and VP function can be carried out. At that time, if VP function is inadequate, definitive management can go forward (e.g., pharyngeal flap surgery or the revision of a flap that is already in place).

Both before and after Le Fort I osteotomy, VP function is rated as adequate, borderline, or inadequate:

- *Adequate function* is defined as normal nasal resonance, normal nasal air emission, and adequate VP closure during speech.
- *Borderline function* is defined as normal nasal resonance or clinically insignificant hypernasality, inaudible nasal air emission (via mirror test), and borderline or marginal VP closure during speech. Patients with this level of functioning usually have small pinhole gaps in the VP valve through which bubbles, barium, or mucus is observed during videofluoroscopy, nasoendoscopy, or both.
- *Inadequate function* is defined as clinically significant hypernasal resonance, nasal air emission, and VP insufficiency during speech.

Patients without clefting and those with repaired cleft palates who present with maxillary deficiency and adequate preoperative VP closure seem to have enough adaptability in the pharyngeal and soft palate muscles to maintain VP closure after Le Fort I advancement. In general, patients with either a repaired cleft palate or those who have undergone uvulopalatopharyngoplasty and who have only borderline VP closure do not have the same adaptability of the soft palate musculature to achieve valve closure after Le Fort I advancement. Thus, they are at higher risk for the development of clinical VPI. Patients with repaired cleft palates and maxillary deficiency or those with obstructive sleep apnea who have undergone uvulopalatopharyngoplasty and who are considered to have inadequate VP closure before Le Fort I advancement are expected to have the same degree of poor closure after surgery.

Conclusions

When managing a dentofacial deformity with malocclusion, the achievement of a successful outcome and a high level of patient satisfaction requires a thorough understanding of issues related to speech, mastication, and swallowing.

A review of the literature shows significant associations between misarticulated speech and Angle Class II, Angle Class III, and anterior open-bite malocclusions. As long as the other aspects of the speech mechanism are not at fault, the correction of misarticulations through successful orthodontics and jaw surgery is the rule.

A competent VP valve is also an important aspect for the production of intelligible speech. The individual with a repaired cleft palate and maxillary deficiency who is only able to achieve borderline VP closure is at higher risk for the development of VP insufficiency after Le Fort I advancement.

With interdisciplinary evaluation that takes into account speech, mastication and swallowing, the most effective care can be rendered to the individual with a jaw deformity and malocclusion.

- Conclusions

Incidence of Temporomandibular Disorders in the General Population and the Basic Treatment Approach

The prevalence of temporomandibular disorders (TMDs) in the general population as reported in the literature varies widely. It is estimated that an average of 32% of the population reports at least one symptom of TMD, whereas an average of 55% demonstrates at least one clinical sign.* Schiffman and colleagues completed a cross-sectional epidemiologic study that indicated that, at any given time, between 40% and 75% of individuals who were not currently seeking treatment had at least one sign of TMD, and about one third of individuals reported at least one symptom of TMD.[296] Mongini and colleagues documented a prevalence of TMD symptoms in children and teenagers of 12% and 20%, respectively.[210] Wanman and colleagues showed an incidence of joint noise in young adults in their late teens to be as high as 17.5% over a 2-year period.[345] TMDs remain a frequent cause of visits to primary care physicians, otolaryngologists, internists, and pediatricians. Despite the high incidence of TMDs, their natural history suggests that, in up to 40% of patients, symptoms resolve spontaneously.[296]

TMD includes various signs and symptoms of the temporomandibular joint (TMJ), the masticatory muscles, and related structures (Figs. 9-1 through 9-8). These may include a spectrum of referred head and neck pain; joint noise (e.g., popping, clicking, crepitus); reduced or altered mandibular range of movement as a result of muscle spasm or disc displacement; condylar head erosion; and direct pain on palpation of either the TMJ or the masticatory muscles. The signs and symptoms associated with TMDs can also lead to misdiagnosis.[16,112,171,216,342]

A wide variety of often contradictory "conservative" treatment modalities (i.e., non-invasive or potentially

reversible) have been recommended to alleviate the symptoms of TMD and to prevent recurrence.* Enthusiasm by clinicians for the direct surgical alteration of the structures that comprise the TMJ to treat TMD have waxed and waned over the past half century.[60,71,141,143,200,222,241,344] Occlusal factors (i.e., degrees of malocclusion) are often claimed to be associated with TMD. Although it is sometimes stated that orthodontic treatment increases the prevalence of TMD, it is also claimed that orthodontic maneuvers (for at least some types of malocclusion) may reduce the signs and symptoms of TMD. Studies document that the correction of a baseline jaw deformity with malocclusion through orthodontics and orthognathic surgery improves the presenting TMD in the majority of the treated patients, whereas a minority get worse.[6,29,31,67,102,131,152,232,236,347,349,356,359] This is described in greater detail later in this chapter.

Mandibular Range of Motion

The expected normal mandibular range of motion and inter-incisor mouth opening is discussed periodically in the literature.[9,70,93,115,146,179,197,234,235,249,308,309,311-313,315,316,318] Even a 6-year-old child can often open the mouth to a maximum 40 mm or more. Measurements of maximum vertical mouth opening with and without discomfort are considered useful parameters of TMJ health. A restricted mouth opening is considered by many to be a distance of less than 40 mm. Only 1.2% of young adults open their mouths less than 40 mm. However, 15% of the healthy elderly population open their mouths less than 40 mm. Any lateral or protrusive movement of less than 8 mm is considered restricted, although the significance of this measurement is unclear.

Review of Occlusal Factors and Association with Temporomandibular Disorders

Clinicians from a spectrum of medical and dental specialties often consider malocclusion to be the major etiologic factor of TMD.† An assumed strong association between TMD and the malpositioning of the teeth serves as one reason why the diagnosis and treatment of TMD is generally considered within the purview of dentistry. Many of the therapeutic options for the treatment of TMD are based on the idea of "normalizing" or "neutralizing" the

occlusion.[135,355] Common treatment approaches to do so include the reversible use of an occlusal appliance or definitive techniques such as occlusal adjustment (equilibration), restorative dentistry, orthodontics, and orthognathic surgery. Concurrently, it is also true that either the onset of TMD or the worsening of current symptoms is frequently blamed on any one of the previously mentioned treatment regimens.

The dental literature contains clinical studies and reports that claim there are causal relationships between occlusal factors and the symptoms and signs associated with TMD. Egermark-Eriksson and colleagues examined 402 children and reported an association between signs and symptoms of TMD, specific malocclusions (i.e., Class II, Class III, anterior crossbite, and anterior open bite), and occlusal supra-contacts.[87] Brandt studied 1342 children and found a correlation between TMD and degrees of overbite (deep and open) and overjet.[33] Nilner examined 749 teenagers and young adults and reported an association with centric relation (CR)–centric occlusion (CO) discrepancies (i.e., slides), balancing-side contact slides, and symptoms and signs of TMD.[220] Confusion in the literature arises as independent research studies have drawn contrary conclusions. DeBoever and colleagues examined 135 individuals with signs and symptoms of TMD and found no specific associations with malocclusion.[59] Gunn and colleagues similarly found no association between TMD and occlusion in 151 migrant children that they studied.[121] Dworkin and colleagues examined 592 individuals within a specific health maintenance organization and found no association between TMD signs and symptoms and specific occlusions.[80]

In their review article, Seligman and Pullinger pointed out that the majority of existing clinical research (up to that point in time) did not support a clear relationship between occlusion and TMD symptoms.[302] They further clarified that the majority of published research relied on symptom-based data rather than discrete disease classifications. Seligman pointed out that symptoms like joint sounds (e.g., popping, clicking, crepitus) and pain (e.g., in the TMJ region and the masticatory system) lack specificity.[303] In addition, most published studies did not differentiate between TMD diagnostic categories (e.g., disc displacement, myalgia, TMJ osteoarthritis). Most published studies also suffered from a lack of or an inadequate control group. Seligman and colleagues attempted to avoid these shortcomings by completing a multifactorial analysis of the risks and relative odds of an individual having a TMD as a function of 1 of 11 common occlusal features.[259,304] They looked for correlations between each of these 11 specific occlusal factors (Box 9-1) and 1 of 6 TMJ diagnostic categories (Box 9-2), including asymptomatic normal controls without TMD.[259]

The asymptomatic control subjects (N = 147) were considered the reference standard because they were without current symptoms or signs of TMD and because they had no history of TMD. Occlusal findings in the symptomatic group showed wide variations, including the following:

- Overjets ranging from –1 to +6 mm
- Overbites ranging from –2 to +10 mm
- Midline discrepancies of up to 5 mm
- Anteroposterior molar relationships from –6 to +6 mm
- Molar asymmetries of 0 to 6 mm
- CR–CO slides of up to 2 mm

There were also a wide variety of crossbites, asymmetrical slides, posterior contacts, and severe attrition facets in the control group. Interestingly, no anterior open bites were found in the control group.

The authors concluded that what have been traditionally considered malocclusions cannot be used to define or

• BOX 9-1

Occlusal Features and Factors to Consider in TMD*

1. Anterior open bite
2. Maxillary lingual posterior crossbite
3. Retruded centric position–inter-contact position slide length
4. Retruded centric position–inter-contact position slide asymmetry
5. Unilateral retruded centric position contact
6. Overbite
7. Overjet
8. Dental midline discrepancy
9. Number of missing posterior teeth
10. First molar relationships (i.e., the greater of the mesiodistal maxillary discrepancies at the first molar location)
11. Right versus left first molar position asymmetry

• BOX 9-2

Temporomandibular Joint Diagnostic Categories to Consider in TMD*

1. Disc displacement with reduction (N = 81)
2. Disc displacement without reduction (N = 48)
3. Temporomandibular joint osteoarthrosis with disc displacement history (N = 75)
4. Primary osteoarthrosis (N = 85)
5. Myalgia only (N = 124)
6. Asymptomatic normals (N = 147)

*Data from Pullinger AG, Seligman DA, Gornbein JA: A multiple logistic regression analysis of the risk and relative odds of temporomandibular disorders as a function of common occlusal features. *J Dent Res* 72:968–979, 1993.

predict either individuals with TMD or those who are or will become asymptomatic. No single occlusal factor was able to differentiate a TMD patient from a healthy subject. The authors did identify four specific occlusal features that occurred mainly in individuals who were symptomatic with TMD (see diagnostic categories 1 through 5) and that were rarely found in those who were asymptomatic for TMD (see diagnostic category 6). The occlusal features that primarily occurred in individuals with symptomatic TMD included the following:

1. The presence of a skeletal anterior open bite
2. CR-CO slides of more than 2 mm
3. Overjets of more than 4 mm
4. Five or more missing and unreplaced posterior teeth

Pullinger and colleagues concluded that occlusion cannot be considered the most important factor in the definition of TMD but that specific occlusal factors do make biologic contributions to TMD and thus cannot be ignored.[254-261] In most individuals, they observed that the human biologic system will adapt to a variety of malocclusions in an attempt to achieve TMJ stability. The authors surmised that some occlusal features will place greater adaptive demands on the individual's biologic system than others. Although most individuals are able to compensate for their occlusal disharmony without problems, adaptation for others may lead to a greater risk for TMD. On the basis of this data, the authors stressed the importance of five occlusal conditions, which in isolation or combination are more likely to reach the threshold that exceeds adaptation for an individual and therefore results in TMJ dysfunction. The high-risk malocclusions are discussed later in this chapter.

Occlusal Conditions More Frequently Associated with Temporomandibular Disorders

Anterior Open Bite

Research by Pullinger and colleagues showed a strong relationship between osteoarthritis of the condylar head with a loss of condylar height and an anterior open-bite malocclusion.[254-261] Interestingly, anterior open bite was not commonly associated with disc displacement disorders with or without reduction. Myalgia (i.e., masticatory muscle discomfort) was also a frequent symptom among patients with an anterior open bite. It is not stated in what percentage of individuals the anterior open-bite malocclusion occurred only secondarily as a result of osteoarthritis followed by a loss of condylar height with clockwise rotation of the mandible. Therefore, it is unclear what percentage of the examined individuals with anterior open bites had these finding as part of a developmental jaw deformity.

Overjet (>6 to 7 mm)

In the patients that were studied, an overjet of more than 4 mm was more likely to be associated with osteoarthritis. Only when the overjet was more than 6 mm was there an association with disc displacement. The occurrence of a progressive overjet in adults would be suggestive of active condylysis. It was not stated in what percentage of those individuals with significant overjet (i.e., >6 to 7 mm) the occlusal feature was part of a developmental jaw deformity rather than occurring secondarily only after condylysis with a loss of condylar height.

Centric Relation–Centric Occlusion Slides

Limited occlusal slides (i.e., 1 mm) were common in all patient groups, including the normal controls. CR–CO slides of more than 2 mm were only found in the patients with TMDs. Pullinger found that larger slides were frequently associated with osteoarthritis of the condylar head. He questioned the advisability of the clinicians' automatic attempt to "relieve" the occlusal slides in all individuals—whether by irreversible (e.g., occlusal equilibration, orthodontics, surgery, restorative dentistry) or reversible (e.g., occlusal splints) means—because the observed slide may be either adaptive or inconsequential.[260]

NOTE: The studies by Pullinger and colleagues seem to confirm that the occlusal features of anterior open bites; overjets of more than 6 mm; and CR–CO slides of more than 2 mm are frequently seen in conjunction with osteoarthritis (i.e., loss of condylar height) and less commonly seen with disc displacement disease. Unfortunately, it is not clearly stated which came first: a developmental deformity with malocclusion and then osteoarthritis or condylysis with the loss of posterior facial height that results in a secondary jaw deformity with malocclusion.

Unilateral Maxillary (Lingual) Crossbite

The occlusal feature of unilateral maxillary crossbite occurs in about 10% of the adult population, and it is frequently found in association with TMJ disc displacement with or without disc reduction. Approximately 25% of the patients with non-reducing disc displacements were found to have unilateral maxillary lingual crossbites. This indicated to Pullinger and colleagues that disc displacement may be a biologic adaptive response of the individual to a unilateral maxillary lingual crossbite.[260] The investigators theorized that these individuals may later be prone to osteoarthritis. They suggested that the orthodontic treatment of a unilateral crossbite discovered during childhood should be considered as a preventative measure to reduce the adaptive demands on the masticatory system. They did not come to the same conclusion for the correction of a longstanding

unilateral posterior crossbite in an adult, because skeletal adaptation would have already occurred. Unfortunately, the investigators did not clarify if the crossbites in their study patients were the result of developmental jaw deformities (e.g., asymmetrical mandibular excess) or simply due to the malpositioning of the teeth. They did not specifically comment on whether orthognathic surgery should be carried out in conjunction with orthodontics (if needed) in young adults to correct the presenting malocclusion as a way to prevent the progression of TMD.

Missing Posterior Teeth (≥5)

The investigators found that, when five or more posterior teeth were missing, the incidence of TMD increased. This includes TMD categories of both osteoarthritis and disc displacement with or without osteoarthritis. Pullinger and colleagues further claimed that, when two or four of the "posterior teeth" (bicuspids) were removed as part of an orthodontic treatment protocol, there was a negligible effect on TMD.[260] Other studies carried out by Kayser[156] and Witter[354] have also documented acceptable masticatory function after bicuspid extractions and orthodontic treatment without increased signs and symptoms of TMD.

NOTE: The multifactorial analysis of occlusal factors and TMD disease categories carried out by Pullinger and colleagues showed that, except for the few clearly defined occlusal features described previously, there was a low probability of a malocclusion being associated with TMD. Seligman and colleagues estimated that the overall contribution of occlusal factors for the defining of patients with TMD was only in the range of 10% to 20%.[302] The corollary is that 80% to 90% of the causative factors cannot be explained by patients' presenting malocclusions.

In the Pullinger and Seligman study, it must be assumed that many of the significant overjets observed in the adult subjects were secondary deformities after condylar resorption (i.e., condylysis).[260] The authors did not present evidence to suggest that the presence of significant overbite or overjet plays a role in the pathophysiology of non-arthritic disorders of the TMJ, and they did not show that it was a causative factor in the observed osteoarthritis. They do believe that a combination of unilateral retruded centric position in the presence of a clinically apparent retruded centric position–inter-contact position slide may encourage TMJ disc displacement but that unilateral retruded centric position per se is not associated with TMD. They found that lost molar support (i.e., 4 or 5 posterior teeth) may be associated with osteoarthrosis. They concluded that a dental midline discrepancy is not a predictor of TMD development during adulthood. Anterior open bite is frequent in the presence of condylysis or osteoarthritic changes in the TMJ, but it is probably the result of (rather than the cause of) the osteoarthritic changes. Interestingly, when open bites are observed in children, they are rarely associated with TMJ symptoms. In the pediatric population, the majority of observed open bites represent a developmental jaw deformity rather than a result of osteoarthritis. Nevertheless, it is recommended that, when either a child or an adult is found to have an anterior open bite, radiographic analysis of the condylar head should be undertaken to check for osteoarthritic changes.

Orthodontic Treatment and Its Effects on Temporomandibular Disorders

Review of the Literature

The relationships among malocclusion, orthodontic treatment to improve the occlusion, and the effects on TMD is discussed frequently in the literature.* A spectrum of orthodontic treatment philosophies has been championed by individual practitioners on the basis of presumed effects on TMD. The longitudinal nature of orthodontic treatment, which is often carried out over several years, means that a changing TMD history would also be expected in a control group that is not simultaneously undergoing orthodontic treatment. Therefore, the occurrence of joint noise (e.g., popping, clicking) or myalgia (i.e., masticatory muscle discomfort) during orthodontic treatment may either be the result of the treatment or consistent with the natural history of the untreated individual.

Sadowsky and colleagues reported on 75 adult study patients who had undergone orthodontic treatment with full appliances during adolescence at least 10 years earlier.[290] The treated group was compared with a group of 75 similar adults with untreated malocclusions. The authors also went on to increase both their control and subject groups and to report these additional findings several years later.[291] In the two sequenced studies, respectively, 15% to 21% of the treated subjects presented with one or more signs of TMD (e.g., joint noise), and 29% to 42% had at least one or more symptoms of TMD. There were no statistically significant differences between the treated and untreated (control) groups.

Larsson and colleagues evaluated 23 individuals who had undergone orthodontic treatment during adolescence at least 10 years earlier.[172] Mild TMD was recorded in 8 out of 23 (35%) of the patients, whereas only 1 (4%) had severe TMD. The authors compared this with published epidemiologic controls and stated that there was no difference in the incidence of TMD in the treated group versus the control group.

Dahl and colleagues examined 51 subjects 5 years after the completion of orthodontic treatment and compared them with an untreated control group.[54] The authors found

*References 2, 3, 19, 34, 35, 42, 45-49, 52, 68, 69, 84, 89, 90, 104, 107-109, 127, 134, 137, 138, 150, 155, 159, 164, 168, 169, 182, 184, 185, 203, 224, 237, 240, 245, 253, 268, 271-276, 279, 281, 282, 288-291, 323, 325, 329-332, 334, 352, 358

no statistical differences in TMD between the two groups. The number of subjects in both groups who had at least one mild TMD symptom was relatively high (70% in the treated group versus 90% in the untreated group). Mild symptoms (e.g., joint noise), masticatory muscle fatigue, and stiffness in the lower jaw were frequently observed in both groups.

A study by **Smith and Freer** examined 87 individuals who were treated with full orthodontic bracketing during adolescence.[320] The treatment group (N = 87) was compared with an untreated control group (N = 28). Four years after treatment ended, TMD symptoms were found in 21% of the treated group and 14% of the control group; this was not found to be statistically significant. The one symptom that was statistically more common in the treatment group was a "soft click" (64% of the treated group versus 36% of the untreated group).

Rendell and colleagues examined 462 individuals (90% adolescents and 10% adults) who were undergoing orthodontic treatment in a graduate orthodontic dental school clinic.[267] With the use of a modified Helkimo Index, only 11 of the patients presented with TMD signs or symptoms before treatment. Of the other 451 patients, during the 18-month study, none developed TMD signs or symptoms. For those with preexisting TMD signs or symptoms (N = 11), there was no consistent change in the level of pain or dysfunction reported during treatment.

Kremenak and colleagues reported pretreatment and posttreatment TMD examination data from 109 patients who were treated with full orthodontics.[166,167] The Helkimo Index scores were also compared. No statistically significant differences were noted between the subjects' pretreatment and posttreatment scores. Ninety percent of the patients had Helkimo Index scores that either remained the same or improved, and 10% of the treated patients had scores that worsened. The authors concluded that the orthodontic treatment provided to their patients was not an important etiologic factor for the development of TMD.

Hirata and colleagues examined 102 individuals before and after orthodontic treatment for signs and symptoms of TMD.[128] They compared their treatment group with 41 untreated controls who were matched for age. The incidence of TMD for the treatment and control groups was not statistically significantly different.

Studies have also been carried out to evaluate specific orthodontic treatment maneuvers and their relationship to TMD symptoms and signs. The studied orthodontic maneuvers include the type of orthodontic mechanics used; extraction versus non-extraction therapy; orthodontic treatment and posterior condylar displacement; and orthodontic treatment focused on classic gnathologic principles.

NOTE: In the studies that were reviewed, no consistent benefits or causative factors of TMD were identified on the basis of any specific orthodontic treatment maneuvers carried out in the treatment group as compared with controls.

Orthodontic Treatment Undertaken Specifically to Relieve Temporomandibular Disorders

In everyday dental practice, the establishment of a preferred intra-arch morphologic relationship of the teeth and then the achievement of a satisfactory inter-arch relationship of the teeth in one jaw to those in the other jaw (i.e., occlusion) serves as the basis of treatment objectives. According to a review of the literature, the establishment of a "normal" occlusion through orthodontic mechanics or via other dental means carried out for the purpose of eliminating or preventing the worsening of TMD does not seem warranted. Pullinger and Seligman have stated five potential exceptions to this, which were described previously in this chapter.[255-261] McNamara and colleagues also stated that prudent basic dental treatment objectives will generally include the establishment of the six keys to ideal occlusion as advocated by Andrews, when feasible; the establishment of a limited CR–CO slide (i.e., <2 mm); the limiting of an anterior open bite; the alleviation of significant overjet (i.e., >6 to 7 mm); the limiting of unilateral maxillary lingual crossbites in children; and the establishment of a stable posterior occlusion.

Orthodontic Treatment Undertaken Specifically to Prevent Temporomandibular Disorders

The literature also contains studies that suggest that specific orthodontic maneuvers are effective for the prevention of TMD. The studies by Magnusson and colleagues[187-192] and the study by Egermark and colleagues[89] suggest preventative TMD advantages related to orthodontic occlusal corrections. At 5 and 10 years, these investigators reevaluated a group of 402 children and adolescents who had originally undergone a full course of orthodontic treatment. The Helkimo Index was used to measure clinical signs of TMD in the now older age group (i.e., ≥25 years old). Interestingly, the Helkimo Index outcome was lower in those who had undergone orthodontic treatment as compared with the control group. The studies by Dahl and colleagues and Sadowsky and colleagues also demonstrated a trend (although not a statistically significant one) toward the decreased prevalence of TMD signs and symptoms in orthodontically treated patients.[53,290,291] These studies would require further confirmation before accepting them as credible indications of a cause-and-effect relationship.

Summary of Effects of Orthodontic Treatment on Temporomandibular Disorders

McNamara, Seligman, and Okeson summarize their understanding of the relationship between orthodontic treatment and TMDs as follows[203]:

1. Signs and symptoms of TMD do occur in healthy individuals.

2. Signs and symptoms of TMD increase with age, particularly during adolescence.
3. Orthodontic treatment performed during adolescence generally does not increase or decrease the odds of developing TMD later in life.
4. The extraction of teeth as part of an orthodontic treatment plan does not increase the risk of TMD.
5. There is no elevated risk for TMD associated with any particular type of conventional orthodontic mechanics.
6. Although a stable occlusion is a reasonable orthodontic treatment goal, the inability to achieve a specific gnathologic ideal occlusion does not result in TMD signs or symptoms.
7. No specific method of TMD prevention has been demonstrated to be effective.
8. When more severe TMD signs and symptoms are present, simple forms of treatment can alleviate them in most patients.

NOTE: McNamara, Seligman, and Okeson suggest that until reliable criteria are developed for the treatment of TMD, the dental and medical professions should be encouraged to manage presenting TMJ symptoms with reversible therapies and to only consider permanent alterations in the occlusion (for the specific purpose of treating or preventing TMD) in patients with very unique circumstances. This is in agreement with the National Institute of Health conference guidelines which states that reversible therapies should be used in the primary treatment of TMD[219]

A summary of evidence-based systematic reviews of TMDs was carried out by Rinchuse and McMinn.[283] Their systematic review resulted in the following conclusions:

1. Occlusion, which was once considered the primary and sole cause of TMD, now at best is recognized as having a secondary role in causing it.
2. Conventional orthodontic treatment that improves the occlusion does not cause TMD.
3. The use of occlusal adjustments in orthodontic patients has no evidence-based support for the treatment of TMD.
4. There is evidence-based support for the use of occlusal splints and biofeedback for the treatment of TMD.

Association of Jaw Deformities, Orthognathic Surgery, and Temporomandibular Disorders

Review of the Literature

The association of a jaw deformity with malocclusion and the effects of orthodontic and surgical correction on TMD signs and symptoms have been examined in clinical studies for the past several decades.* The quality of the research and therefore the value of the conclusions vary. There are just three longitudinal prospective controlled clinical trial studies that have been carried out to assess the effects of orthognathic surgery on TMD: the studies by Onizawa and colleagues,[232] Panula and colleagues,[236] and Dervis and colleagues.[67]

The study by **Onizawa and colleagues** sought to evaluate changes in the symptoms of TMD after orthognathic surgery.[232] TMJ symptoms in preoperative orthognathic patients (N = 30) were compared with those of healthy control volunteers (N = 30). Changes in TMD symptoms were evaluated in both groups at 3- and 6-month postoperative intervals. The authors found no significant differences in the incidence of TMJ sounds, deviation of mouth opening, or tenderness on direct palpation of the TMJ and masticatory muscles between patients who were scheduled to undergo orthognathic surgery and control volunteers. The treatment group did not report TMJ symptoms significantly more often than the control subjects. At both the 3- and 6-month postoperative intervals, half or more of the treatment group showed no change in TMJ sounds, deviation of mouth opening, or tenderness on palpation of the TMJ or masticatory muscles. At each evaluation time frame, some individuals in both the control group and the study group exhibited improvement in TMJ symptoms, whereas others showed a change for the worse. Findings of postoperative TMJ sounds were observed to be associated with a reduction of mandibular mobility (i.e., mouth opening). The authors concluded that TMD symptoms did not always show improvement after surgical correction and that, for some patients, the symptoms changed for the worse.

Panula and colleagues carried out research to study the effects of orthognathic surgery on TMJ dysfunction.[236] They completed a prospective follow-up study to examine the influence of orthognathic procedures for the correction of dentofacial deformities on signs and symptoms of TMJ dysfunction. Sixty consecutive patients with dentofacial deformities were examined preoperatively and then twice after orthognathic surgery. The Helkimo Anamnestic and Dysfunction Indices were also given as a questionnaire, and the results were used as part of the determination. The prevalence of headache was also assessed. The average follow-up was 4 years after the initial preoperative examination. A group (N = 20) with a similar type and grade of dentofacial deformity who elected not to undergo surgical correction or any other occlusal therapy served as the control group. The majority of the treatment group (73%) was found to have signs and symptoms of TMJ dysfunction or TMD during the preoperative examination. At the final

*References 6, 7, 25, 32, 33, 36, 55, 61, 62, 66, 67, 96, 98, 103, 105, 110, 111, 123, 124, 131, 144, 145, 154, 157, 158, 160, 174, 180, 187, 189, 211, 225, 226, 232, 236, 247, 292-295, 322, 335, 340, 347, 349, 350, 353, 356, 359

postsurgery examination (i.e., 4 years after surgery), the prevalence of TMD had been reduced to 60%. There was also a dramatic improvement in the prevalence of headache, which was initially experienced by 63% of patients and reduced to 25% of patients at the final visit. The authors concluded that signs and symptoms of TMD, including pain (headache) levels, could be reduced with orthognathic treatment. The risk of an orthognathic patient experiencing new TMD was extremely low. No association could be shown between TMD and any specific type or magnitude of dentofacial deformity.

A study was conducted by **Dervis and colleagues** with the objective of looking at the long-term prevalence of TMD in individuals with a dentofacial deformity who then underwent orthognathic surgery as compared with a control group.[67] Signs and symptoms of TMD in both the dentofacial deformity patients and the control group were evaluated before surgery, 1 week after release of intermaxillary fixation, and 1 and 2 years after surgery with the use of the Helkimo Anamnestic and Dysfunction Indices. At both the initial preoperative examination and the final examination (i.e., 2 years after surgery), signs and symptoms of TMD in the patients who were undergoing orthognathic surgery were compared with those of healthy control subjects. The lengths of condylar pathways during opening and with lateral and protrusive movements were also evaluated with the use of axiography. A statistically significant reduction of TMD symptoms and signs 2 years after surgery as compared with before surgery was found. Interestingly, at the initial examination, the patients with dentofacial deformities who were scheduled to undergo orthognathic surgery did not report TMD signs and symptoms with a greater frequency than other healthy control subjects. At the final examination (i.e., 2 years after surgery), greater improvements in TMD symptoms in the patients who had undergone orthognathic surgery were found as compared with healthy control subjects. The authors also found a statistically significant decrease in masticatory muscle tenderness after surgery. The authors concluded that the "functional status" of the TMJ can be improved with orthognathic surgery. There was no clear association between TMD symptoms and a specific type or pattern of dentofacial deformity.

When comparing and contrasting the three published longitudinal prospective controlled studies that were conducted to determine the effects of orthognathic procedures on TMD symptoms and signs (i.e., Onizawa and colleagues,[232] Panula and colleagues,[236] and Dervis and colleagues[67]), several observations can be made:

1. Patients with dentofacial deformities who were scheduled to undergo orthognathic surgery were not found to have significant differences in their TMD signs and symptoms as compared with patients in the control groups.
2. After orthognathic surgery and orthodontics, signs and symptoms related to TMD were frequently improved.
3. Despite the trend for diminished signs and symptoms of TMD after orthognathic surgery and orthodontics, individuals did not always show improvement; for some, the symptoms changed for the worse.
4. After orthognathic surgery and orthodontic treatment, a decrease in masticatory muscle tenderness was frequent. A decrease in joint tenderness on palpation was also a common occurrence.
5. In one of the three studies reviewed, a decrease in maximum mouth opening was observed, but this was not found to be of clinical importance.

There are other less rigorous reports and studies that can be found in the literature that also analyze the effects of orthodontics and orthognathic surgery carried out for the correction of dentofacial deformities on TMD, including the following:

Karabouta and colleagues reviewed 280 individuals with different patterns of mandibular deformities (e.g., prognathism, retrognathia, open bite, asymmetry) who underwent orthognathic surgery that included sagittal split ramus osteotomies of the mandible. Before surgery, the patients were found to present subjective or objective TMJ dysfunction symptoms with an incidence of 41%.[154] After surgery, the incidence of such symptoms in the same patients was reduced to 11%. Individuals with no preoperative TMJ dysfunction symptoms developed such symptoms with an incidence of 4% after surgery.

White and colleagues set out to review the prevalence of TMD in patients with dentofacial deformities who were undergoing orthognathic surgery.[349] Preoperatively, 49% of their study group presented with TMD. After orthognathic surgery, in the symptomatic patients, 89% had improved temporomandibular function, 3% were unchanged, and 8% developed increased symptoms. Of the preoperative asymptomatic patients, 8% developed TMD after surgery. In the study group, TMD was significantly greater in patients with Class II skeletal deformities as compared with those with Class III tendencies. Overall, temporomandibular function generally improved in both treatment groups (i.e., Class II and Class III) after successful surgery.

Hori and colleagues reported three individual (nonconsecutive) cases in which there was a worsening of preexisting TMJ dysfunction after sagittal split ramus osteotomy of the mandible and 6 weeks of intermaxillary fixation.[131] All three of their patients initially presented specifically seeking treatment of malocclusion for the relief of TMD. All three patients had active TMD before and after their orthognathic procedures.

Aghabeigi and colleagues studied the effect of orthognathic surgery on the TMJ of patients who presented with an anterior open bite.[6] This was a retrospective survey study of patients (N = 83) who presented with an anterior open bite who then underwent orthognathic surgery. The preoperative prevalence of head and neck pain was 32%, TMJ dysfunction was found in 40% of patients, and limited mouth

opening was found in 7%. The overall prevalence of TMJ signs and symptoms was not found to be significantly different after orthognathic surgery. In the study group, an abnormal psychological profile was the most significant factor associated with the presence and persistence of TMJ pain. The authors concluded that orthognathic surgery does not significantly influence TMD in patients with anterior open bites. Female patients—particularly those with abnormal psychological profile—were at higher risk for persistent postoperative TMJ pain.

Westermark and colleagues studied a consecutive series of individuals to understand the effects of orthognathic surgery on the signs and symptoms of TMD.[347] The authors sent a survey questionnaire to a consecutive series of patients (N = 1516) who initially presented with dentofacial deformities and who then underwent orthognathic surgeries that were performed by a group of experienced surgeons at a single institution. The survey was given at least 2 years after surgery. The questions asked in the survey related to joint pain, chewing pain, joint noise, grinding, daytime headache, and morning headache. Preoperatively, 43% of the patients reported subjective symptoms of TMD; postoperatively, 28% of the patients did. This difference suggested an overall beneficial effect of orthognathic surgery on TMD signs and symptoms. Patients with Class II skeletal deformities did not improve as much as with those with Class III skeletal prognathism.

Yamada and colleagues studied the incidence of condylar morphologic change, disc displacement, and signs and symptoms of TMD in individuals set to undergo orthognathic surgery.[359] The study showed preoperative condylar morphologic change (unilateral or bilateral) in 36% of the subjects and in 24% of each joint. Preoperative disc displacement (unilateral or bilateral) was seen in 41% of the subjects and in 30% of each joint. The percentage of condylar morphologic change and disc displacement was higher for individuals with anterior open-bite skeletal Class II growth patterns and lower for patients with skeletal Class III deformities.

Wolford and colleagues studied changes in TMD after orthognathic surgery in a series of 25 patients who were scheduled to undergo bimaxillary surgery.[356] They used magnetic resonance imaging and clinical verification of TMJ articular disc displacement. This was a retrospective evaluation with an average follow up of 2.2 years. Presurgically, 16% of the patients had only TMJ pain, 64% had only TMJ sounds, and 20% had both TMJ pain and sounds. Postoperatively, 24% of the patients had only TMJ pain, 16% had only TMJ sounds, and 60% had both TMJ pain and sounds. Thirty-six percent of the patients had TMJ pain preoperatively; this jumped to 84% after surgery. In addition, the authors claimed that 6 out of 25 of their patients (24%) developed condylar resorption postoperatively, thereby explaining the high incidence of observed Class II open-bite malocclusion. The authors demonstrated that patients with preexisting TMJ dysfunction who undergo bimaxillary osteotomies via the techniques that they used have a high probability of the significant worsening of TMJ dysfunction after surgery. This reported high incidence of TMD and condylar resorption after orthognathic surgery is contrary to all other studies reported in the literature.

Borstlap and colleagues reported about a consecutive series of individuals who were scheduled to undergo sagittal split ramus osteotomies for both Class II mandibular retrognathism and Class III mandibular prognathism.[31] Patients were reviewed preoperatively, immediately postoperatively, and at 3, 6, and 24 months postoperatively. Any signs and symptoms of TMD were documented, including clicking, preauricular pain, maximum mouth opening, protrusive movements, and lateral excursions. The authors documented that 56% of the patients with preexisting TMD had relief of their signs and symptoms. Interestingly, 22% of individuals without preexisting TMD went on to develop clinical signs or symptoms after surgery.

Bock and colleagues studied the importance of temporomandibular function as a factor in the achievement of patient satisfaction after orthognathic surgery.[29] The authors' orthognathic surgery patients (N = 102) were examined at an average of 47 months after surgery. The average age of their patients was 24 years. A patient satisfaction questionnaire and other modalities were reviewed, including the Helkimo Index, clinical findings, nerve function parameters, and the incidence of intraoperative and postoperative complications. The results of their study showed that 91% of patients were satisfied or very satisfied with their overall orthognathic results. Answers to the questionnaires revealed that only 79% of patients would undergo treatment again (i.e., 21% of the patients would not). Statistically significant differences were found in the Helkimo Index and in the pain reported both in the TMJs and with jaw movements between the satisfied and dissatisfied postoperative patients. The authors surmised that the 21% of patients who would not undergo treatment again were more likely to have a greater degree of TMD and limitations with regard to mandibular range of movement. Statistically significant differences were found between those who were satisfied and those who were dissatisfied with surgery on the basis of their Helkimo Indices. Those with pain on palpation in the TMJ region and those with pain experienced during motion of the mandible were more likely to be overall dissatisfied with the treatment. The persistence of postoperative symptoms of TMD, including pain, was the single most important correlation with low patient satisfaction.

Frey and colleagues studied the effects of mandibular advancement procedures and counterclockwise rotation on signs and symptoms of TMD.[102] The study patients were followed for a minimum of 2 years after orthognathic surgery. A series of patients with Angle Class II malocclusions (N = 127) who were undergoing sagittal split ramus osteotomies with advancement and counterclockwise rotation of the mandible were studied to evaluate signs and symptoms of TMD at specific intervals after surgery. The results of the study indicate that counterclockwise rotation of the mandible was associated with more masticatory

muscle tenderness early after surgery, especially in those who were undergoing more than 7 mm of advancement. The combination of extensive mandibular advancement with counterclockwise rotation was also associated with increased TMD symptoms early after surgery. Interestingly, all TMJ symptoms declined by 2 years after surgery. The authors conclude that surgical advancement and counterclockwise rotation of the mandible (i.e., sagittal split ramus osteotomy) is associated with a slight increase in masticatory muscle discomfort during initial recovery. All symptomatology tended to decline over time, which suggests that the amount of advancement and the amount of mandibular counterclockwise rotation should not be considered as risk factors for the long-term development of TMD in patients without preexisting symptoms.

Jung and colleagues retrospectively evaluated the effects of bilateral intraoral vertical ramus osteotomies with setback for the management of Class III skeletal patterns on symptoms that are associated with TMD.[152] Patients were evaluated preoperatively and at intervals (i.e., 1, 3, 6, 12, 18, and 24 months) after surgery for specific parameters, including mouth opening, clicking, and TMJ pain. The authors reported that 94% of those with preoperative joint noise achieved resolution. After surgery, 8% of individuals who were free of noise before surgery developed joint noise afterward. On average, mouth opening was 50 mm before surgery and 49 mm 6 months after surgery. Joints that were free of pain before surgery remained so. Those individuals with preoperative TMJ pain remained free of pain at 18 months. The authors concluded that bilateral intraoral vertical ramus osteotomy with setback as a method of managing Class III skeletal deformities was also effective for the relief of undesirable TMJ symptoms (e.g., joint noise, pain) without negatively affecting mouth opening.

Additional thoughts Concerning Effects of Orthodontics and Orthognathic Surgery on Temporomandibular Disorders

It may not be correct to conclude that orthodontic treatment and orthognathic surgery carried out for the correction of a presenting jaw deformity with malocclusion are the responsible factors for any observed reduction or resolution of TMD signs and symptoms.[18] During the decades that have passed since McCarty and Farrar first defined the diagnoses of internal derangement of the TMJ and then described a disc repositioning procedure to treat it, quality research to evaluate their recommended treatment has been scant.[200] The experience of orthopedic surgeons with regard to the treatment of derangements of the knee should remind us of the need for clinical practice to be based on sound supporting evidence. Moseley and colleagues carried out a controlled clinical trial of arthroscopic surgery (i.e., lysis and lavage or arthroplasty) for osteoarthritis of the knee that should give us pause when considering irreversible TMD treatment.[212] Clinician opinions regarding the effectiveness of lysis and lavage or arthroplasty to manage knee pathology in anticipation of improved function and relief of pain have varied but are currently without consensus. Therefore, a randomized clinical trial that included a placebo group was designed by Moseley and colleagues to address this controversy. To blind the placebo group, a sham surgical procedure was designed as part of the study. The placebo subjects were given a general or regional anesthetic, and incisions were made; however, the arthroscope was not inserted into the joint, and no therapeutic procedure was carried out. The results of the study were that neither treatment group (i.e., lysis and lavage or arthroplasty) offered improved clinical outcomes as compared with the placebo group for osteoarthritis. As a consequence of this evidence-based study, many orthopedic surgeons have changed treatment recommendations for their patients. In any case, Medicare (i.e., the U.S. government medical insurance plan for the elderly) made a decision that it would no longer cover arthroscopy for osteoarthritis of the knee. *Restorative dentists, orthodontists, and orthognathic surgeons should remain circumspect when advising patients regarding irreversible treatment specifically for the purpose of relieving TMD.*

Brief Overview of Okeson's Thinking About Temporomandibular Disorders and the Effects of Occlusion

Okeson believes that, during the normal use of the masticatory system, either local or systemic events can occur that may influence function.[165,227-231] Each individual has a varied ability to tolerate these events without any adverse head and neck effects. It is likely that an individual's tolerance can be influenced by these local or systemic factors. When an event exceeds the individual's physiologic tolerance, the system begins to reveal changes. Each component of the masticatory system can tolerate a certain amount of change. When functional change exceeds a critical level, alteration of the tissues begins. The tissue breakdown site is generally seen in the structure with the least tolerance. Therefore, the breakdown site varies from individual to individual. This is influenced by factors such as the individual's unique maxillofacial morphology, previous head and neck trauma, and local tissue conditions. The weakest link in the masticatory system will break first (i.e. masticatory muscles, TMJs, supporting structures of the teeth, the teeth themselves). Typically, the weakest structures in the system are the masticatory muscles; this is evidenced by muscle tenderness and pain during mandibular movements.

When the TMJs are the weakened structures in the system, the individual may experience joint tenderness and pain. The TMJ can also produce sounds such as clicking or grating. When the individual has increased muscle activity (e.g., bruxism, grinding), then the next weakest link is frequently either the supporting structures of the teeth (i.e., the periodontium) or the teeth themselves. The teeth may

show mobility or wear (e.g., loss of enamel, breakdown of restorations, fracture). Emotional stress seems to be a major influence on bruxing activity.

According to Okeson, the occlusal condition can influence TMDs by way of two mechanisms. One mechanism relates to the introduction of acute changes in the occlusal condition (e.g., recent restorative dentistry with an uneven alteration of the occlusal surfaces). Acute changes can lead to a muscle co-contraction response that leads to a condition of muscle pain. Typically, in these circumstances, new muscle engrams are developed, and the patient adapts with little consequence. A second mechanism relates to a more longstanding variation in the occlusal condition. In these conditions, maximum intercuspation (i.e., centric occlusion) results in the instability of the masticatory system (e.g., a CR–CO discrepancy). The orthopedic instability is not likely to withstand significant compressive loading forces on the TMJs. Dental therapy (i.e., the alteration of the occlusion) will only be helpful for the relief of TMDs when it effectively relieves one of these conditions (i.e., the muscle co-contraction response or the orthopedic instability accompanied by loading forces).

Dr. Okeson concludes that, in general, conventional orthodontic treatment is not an effective method for the prevention of TMD. As a corollary, a review of the literature suggests that patients who receive conventional orthodontic therapy are at no greater risk for the development of TMD than those who do not. According to Dr. Okeson's work, any dental or surgical procedure that produces an occlusal condition that is not in harmony with a musculoskeletal stable position of the joint can—but does not necessarily—predispose the individual to these problems. Alternatively, dental or surgical procedures that reduce one of these occlusal conditions and restore harmony may improve the masticatory system.

Personal Thoughts About the Role of Open Joint Procedures for Temporomandibular Disorders

Unanswered questions remain: What is the appropriate treatment for an individual with a persistent symptomatic intracapsular TMJ disorder that has either not resolved spontaneously or not responded to conservative therapy? In these cases, what are the best studies to use to confirm the diagnosis and then select the appropriate treatment intervention?

A critical review of the literature suggests that outcomes for open TMJ procedures are often unpredictable and may result in further TMD.[73-77] The success rate for "redo" open joint surgery is even less favorable. Among the criteria for an open joint procedure are the following: that the clinician must be confident that the source of the pain or dysfunction is arising from within the joint; that the appropriate use of conservative measures has failed; that the current symptoms are intolerable to a patient who is psychosocially stable; and that a significant long-term success rate for the selected open joint procedure in the specific patient can be assured.

Although an intracapsular lavage procedure with or without limited debridement and lysis of adhesions to relieve inflammation and improve function may be relatively benign in experienced hands, disc repositioning and discectomy have generally proven to be of little statistical value as compared with conservative measures. The technical simplicity of disc repositioning and discectomy procedures has lured many clinicians into offering them as standard options; however, a significant long-term success rate has not been documented.

The overall approach to TMD should aim to avoid further harm to the joint and err on the side of appropriate conservative management to relieve symptoms and to achieve or maintain reasonable function for the long term.

Conclusions

It is estimated that an average of 32% of the population will report at least one symptom of TMD and that an average of 55% will demonstrate at least one clinical sign. Historically, clinicians from a spectrum of medical and dental specialties have considered occlusion to be the major etiologic factor for TMD. A review of the literature suggests that the overall contribution of occlusal factors to identifying patients with TMD to only be in the range of 10% to 20%. The corollary is that 80% to 90% of the causative factors among patients with TMD cannot be explained by those patients' occlusions.

The National Institute of Health conference guidelines state that reversible therapies should be used for the primary treatment of TMD. Despite these words of caution, studies document that, for whatever combination of reasons, the correction of an individual's developmental jaw deformity and malocclusion through successful orthodontics and orthognathic surgery tends to have a positive effect on preexisting TMD in the majority of patients, whereas a minority of patients will get worse.

Nasal Airway Considerations in the Evaluation and Treatment of Dentofacial Deformities

JEFFREY C. POSNICK, DMD, MD

- Frequent Causes of Chronic Obstructive Nasal Breathing
- The Effects of Respiratory Pattern and Jaw Posture on Maxillofacial Growth
- Simultaneous Management of Chronic Obstructed Nasal Breathing and the Presenting Dentofacial Deformity
- Approaching the Nasal Airway Through Le Fort I Down-Fracture
- Management of Residual Postoperative Nasal Obstruction
- Effects of Maxillary Arch Expansion and Nasal Floor Recontouring on the Airway
- Comprehensive Approach to Chronic Nasal Airway Obstruction
- Case Presentation
- Conclusions

The efficiency of care for the individual with a dentofacial deformity requires the collaborative management of any presenting upper airway obstruction, facial dysmorphology, and malocclusion or dental rehabilitative needs. At the time of orthognathic surgery, the surgeon has an opportunity to further contribute to the patient's quality of life by seamlessly addressing any longstanding breathing and sinus drainage difficulties that coexist with the jaw deformity. Breathing difficulties may range from isolated symptomatic nasal airway obstruction to obstructive sleep apnea and should not be overlooked. The impact and frequency of the combined occurrence of nasal obstruction, sinus disease, and maxillary deformity have been recognized and discussed in established literature for well over 100 years:

"Irregularities of the teeth being so frequently associated with some pathologic obstruction of the nasal passages or nasopharynx, this fact should ever be present in the operator's mind and suitable examination being made; and in case [as is often found] the oral deformity be complicated by the presence of hypertrophied faucal tonsils, adenoid hypertrophies in the vault of the pharynx, or obstruction of the nasal passages, the orthodontist's work can only be made complete by the assistance of a rhinologist and laryngologist."[2]

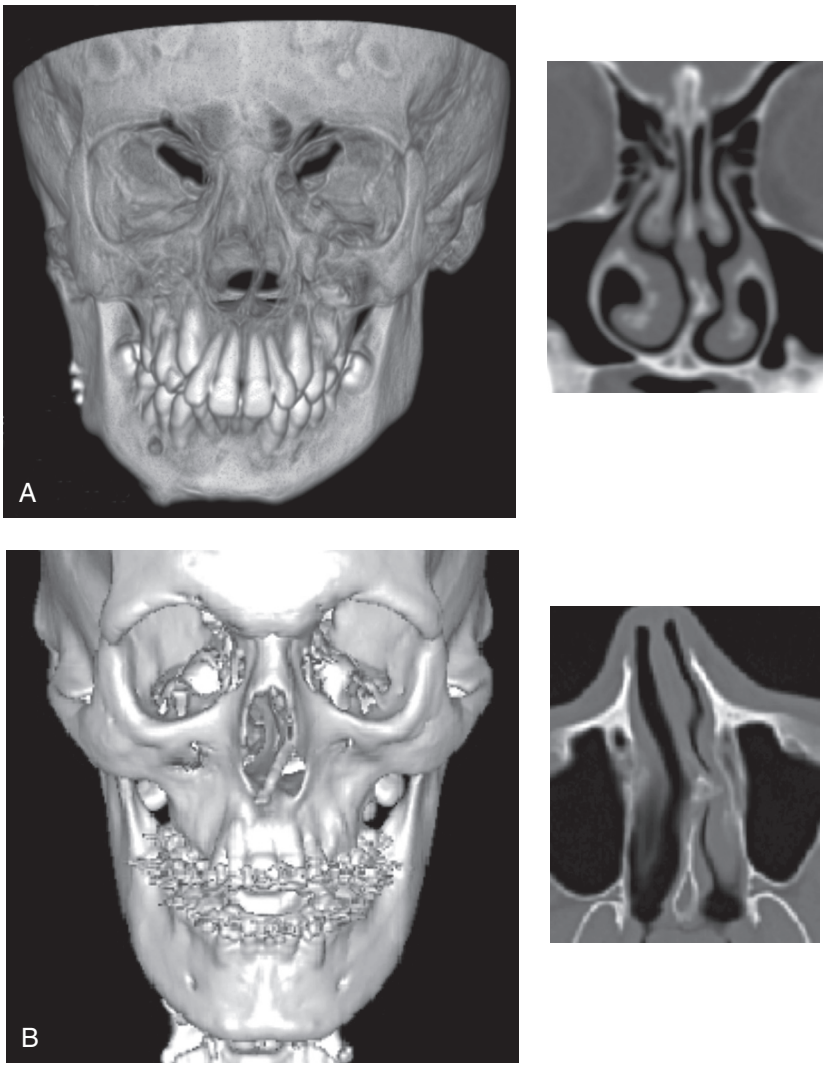
—EDWARD H. ANGLE, MD, DDS (1907)

"The nasal fossae are bounded by the maxillary bones and by bones attached to the maxillae; therefore deformities of maxillary bones are bound to influence the size, shape and patency of the nasal fossae. Nasal obstruction may be due directly to deformity or to lack of development of the maxillae. Any [intranasal] bony [obstructions] are removed [surgically] until ample breathing space is established. If nasal obstruction is due simply to lack of size of the nasal fossae and there are erupted [permanent] molar teeth [on each side], then the treatment consists of placing a jackscrew across the mouth from one upper molar to the other. As the screw is spread, the intermaxillary suture opens, the maxillae separate, and the nasal obstruction is relieved."[10]

—VILRAY PAPIN BLAIR, AM, MD, FACS (1914)

Frequent Causes of Chronic Obstructive Nasal Breathing

Nasal septoplasty is a generic descriptor of the surgical correction of *septal thickenings and deflections* frequently carried out to improve nasal airflow and sinus drainage (Figs. 10-1 and 10-2).[3,7,20,30,52,53,57,75,80,88,89,91,93,94] *Enlarged inferior turbinates* also commonly obstruct nasal breathing and interfere



• **Figure 10-1 A,** Three-dimensional maxillofacial and coronal section computed tomography scan views of a child with mandibular deficiency during late mixed dentition. **B,** Three-dimensional maxillofacial and coronal section computed tomography scan views of a teenager with maxillary deficiency and relative mandibular excess. For both patients, the scans indicate a deviated nasal septum in combination with enlarged inferior turbinates, with an expected increase in nasal airway resistance and diminished breathing space.

with sinus drainage (Fig. 10-3). Hypertrophic inferior turbinates that are only minimally responsive to medical treatment are best managed by partial (surgical) reduction.[8,23,77] A *tight nasal inlet* or constricted pyriform apertures occur in conjunction with a narrow maxillary arch (Fig. 10-4).[58,86,90,95] An *elevated floor of the nose* is a frequent finding in the presence of anterior vertical maxillary excess (i.e., long face growth pattern) (Fig. 10-5).[63,81,112] A *scarred nasal vestibule* seen with a repaired cleft nasal malformation may be another cause of persistent nasal obstruction (Fig. 10-6). Nasal septal deformities, inferior turbinate enlargement, a tight nasal inlet, and an elevated nasal floor all commonly coexist with maxillary deformities (Figs. 10-7 and 10-8).[1,12-14] Favorable access to the nasal septum, the inferior turbinates, the pyriform apertures, and the nasal floor to correct these airway obstructions and deformities is possible through the Le Fort I down-fracture osteotomy that is commonly used in orthognathic surgery (Figs. 10-9, 10-10, and 10-11).[82-85]

Maxillofacial literature has traditionally addressed aspects of nasal obstruction, nasal anatomy, and sinus drainage in the patient who is undergoing orthognathic surgery, but often only in subjective and limited ways.[8,18,24,27,32,33,36,38,55,56,71,73,74,76,103,104,107] Authors traditionally discuss the effects of Le Fort I osteotomies on nasal morphology (i.e., aesthetics) and occasionally recommend adjunctive soft-tissue techniques in the hopes of limiting suboptimal aesthetics (e.g., the alar cinch stitch).[37] Little consideration is given to either baseline upper airway findings or how the maxillary surgery may affect long-term nasal breathing. Warren and colleagues discusses issues of nasal airway changes after Le Fort I osteotomy with maxillary

impaction, advancement, and transverse widening.[108] They used a pressure flow meter to assess nasal airway breathing before and after maxillary osteotomies.[21,29] Turvey and colleagues recognized preexisting nasal obstruction in many of their orthognathic patients.[103] They suggested methods of avoiding adverse effects on nasal airway resistance that may result from Le Fort I maxillary osteotomy procedures.[104] Moses and coworkers reported about a series of patients who were treated for nasal obstruction and sinus drainage difficulties after Le Fort I maxillary procedures were carried out for long face growth patterns (e.g., vertical maxillary excess with anterior open bite).[71] They concluded that Le Fort I impaction frequently aggravates preexisting nasal airway obstruction and sinus disease. Williams and colleagues examined the nasal airway function (breathing) in a consecutive series of subjects (n = 50) before and 5 months after undergoing (1) Le Fort I osteotomy with advancement and vertical lengthening (2) maxillary segmentation with transverse expansion (14 of 50 subjects, 28%); and (3) recontouring of the nasal floor and pyriform rims with a rotary drill. Despite these favorable nasal airway surgical maneuvers, when ignoring potential pathology of the septum (e.g., buckling and deviation) and the inferior

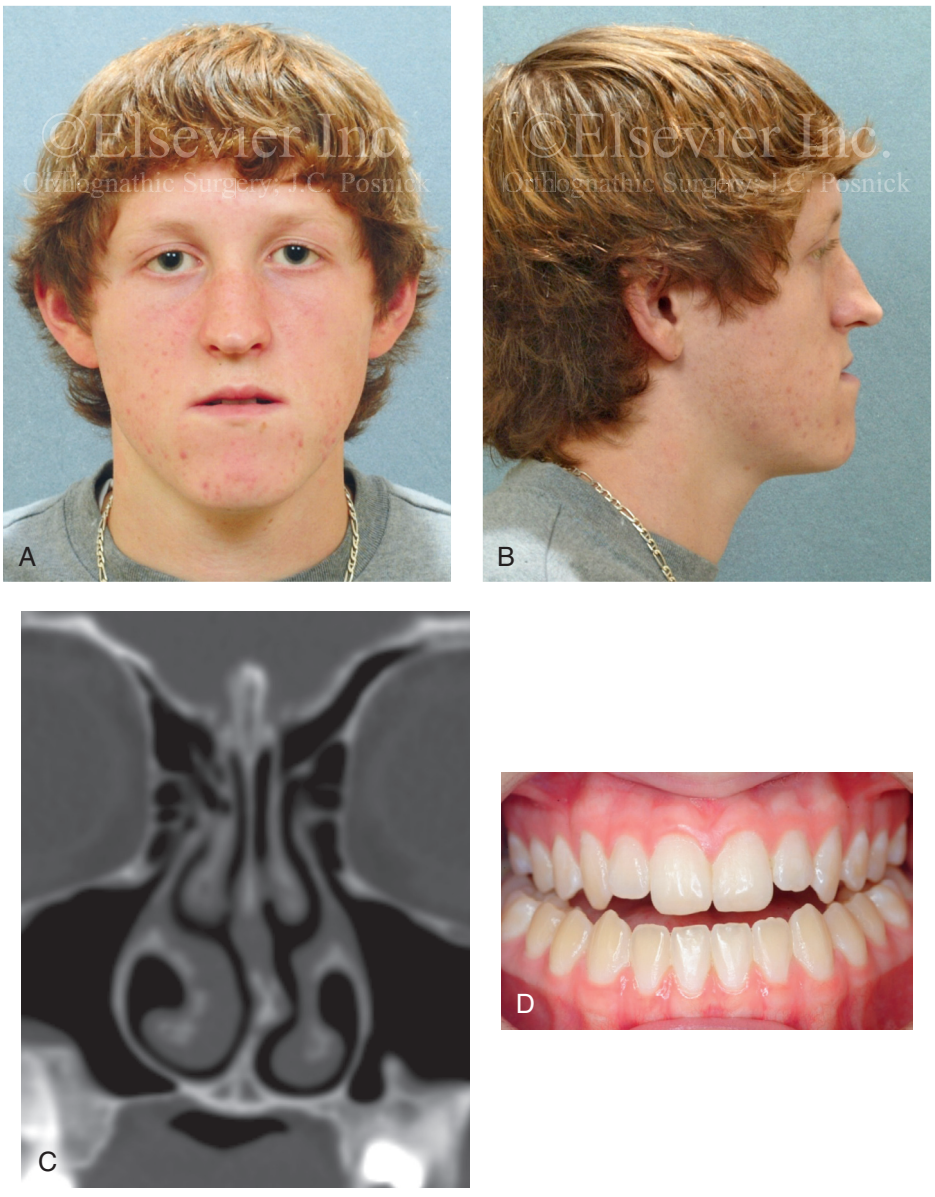
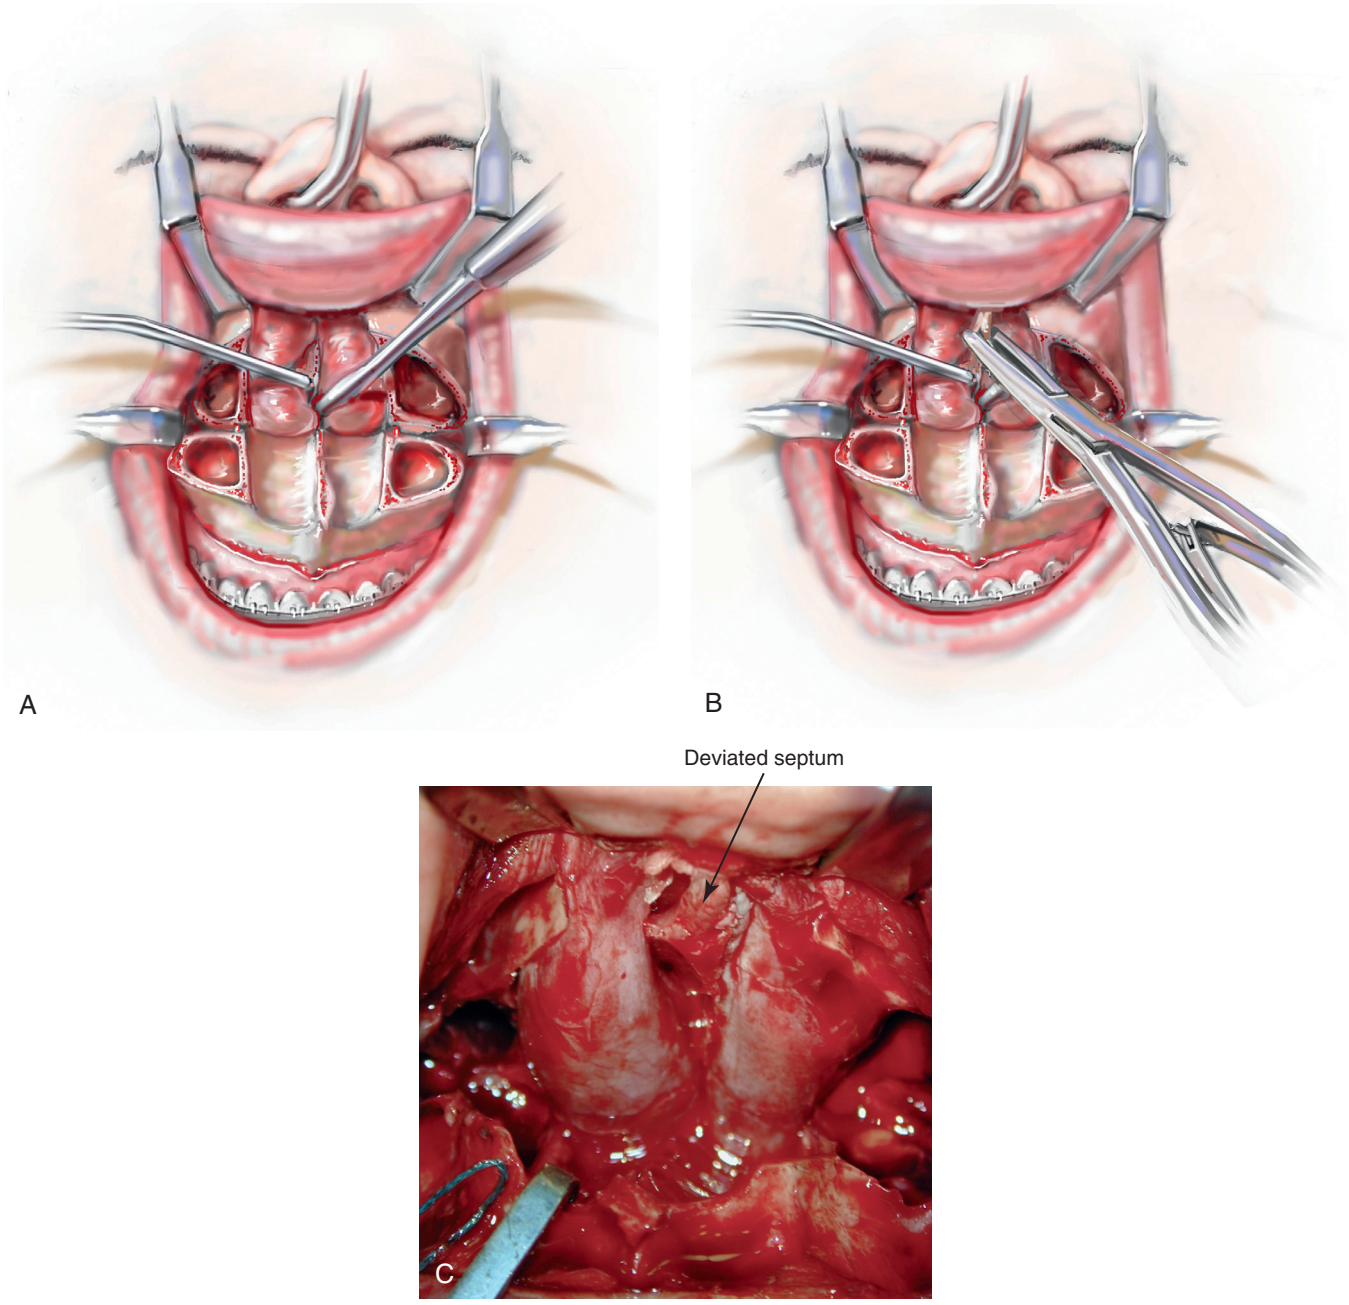
• **Figure 10-6** Individuals born with cleft lips and palates who have undergone primary repair and secondary reconstruction may present with constrictions of both the internal and external nasal valves. This may be worse as a result of the surgical maneuvers that were previously carried out. Two children with bilateral cleft lip and palate and one with unilateral cleft lip and palate are shown to demonstrate this point. Nasal soft-tissue procedures—including "columella lengthening" in the cases of the bilateral cleft lips and palates and the overzealous resectioning of nasal soft tissues in the case of the unilateral cleft lip and palate—were performed. In all three cases, the nasal valves are constricted (i.e., there is airway obstruction), and the aesthetics are suboptimal.

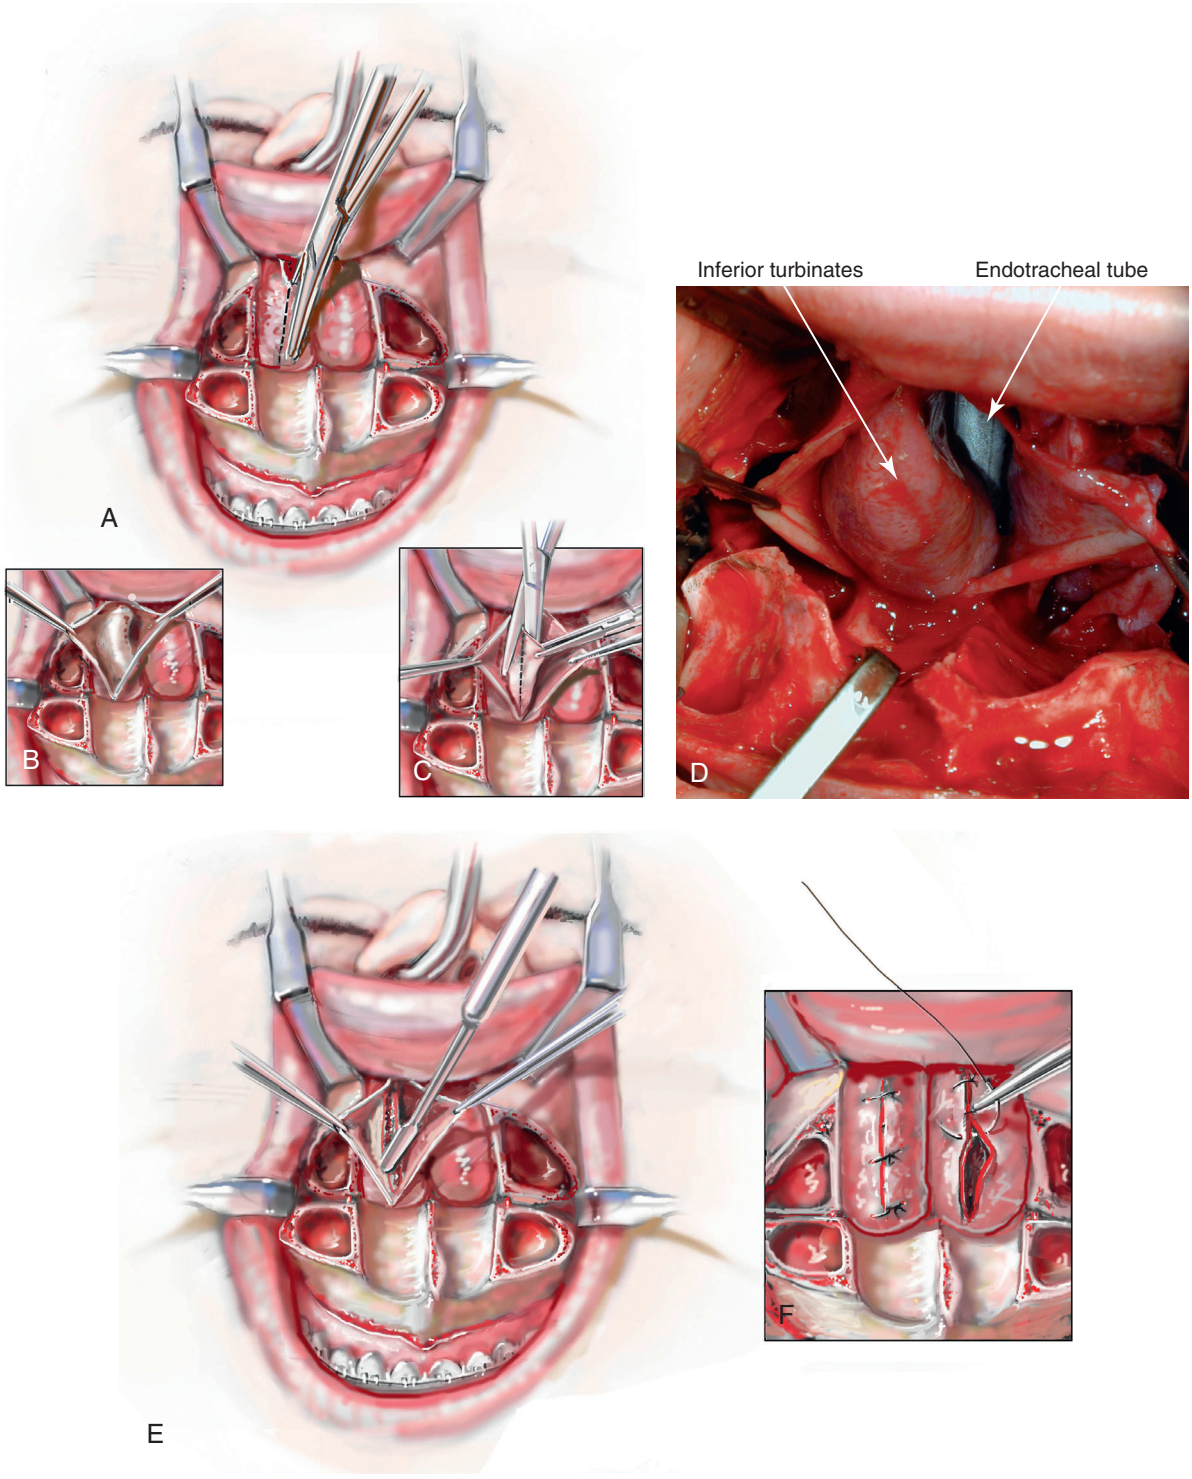
• **Figure 10-7** **A** and **B,** A teenage girl with unilateral cleft lip and palate shows multiple causes of nasal obstruction. These include—as shown in **C** and **D**—septal deviations, inferior turbinate hypertrophy, nasal aperture narrowing, and nasal floor deformities, including a residual unrepaired alveolar cleft.



• **Figure 10-8 A** and **B,** A teenager with a maxillary deficiency and a relative mandibular excess growth pattern. **C** and **D,** The physical findings of septal deviations, inferior turbinate hypertrophy, and a narrow (tight) nasal aperture are consistent with the patient's history of nasal airway obstruction.



• **Figure 10-9** Illustrations and intraoperative view of a deformed nasal septum seen through a Le Fort I down-fracture. This is a demonstration of the technique used to carry out the submucous resection of septal bone and cartilage. When indicated on the basis of the patient's history and clinical examination, attention is turned to the removal of the deviated portions of the septum of the nose. **A,** With an elevator, the submucosal dissection of the cartilaginous (quadrangular cartilage) and bony (vomer and perpendicular plate of ethmoid) septum is carried out. **B,** The deviated and thickened aspects of the cartilaginous and bony septum are resected with a rongeur. The more anterior components of the cartilaginous septum that provide needed support to the nasal dorsum and tip are not disturbed. This includes at least 1 cm of the dorsal and caudal cartilage. **C,** An intraoperative view through a Le Fort down-fracture shows a deviated septum.



• **Figure 10-10** Illustrations and intraoperative view of inferior turbinates seen through a Le Fort I down-fracture. turbinates (e.g., hypertrophy/enlargement), a full 20% of their study subjects experienced a worsening of their nasal airway function after surgery.[113a]

Unfortunately, in the individual with a dentofacial deformity, a methodic approach to the evaluation and management of chronic nasal airway obstruction at the time of orthognathic surgery is often not undertaken. We suggest that any upper airway obstructions be assessed by the orthognathic surgeon with the same vigor as the effects of the presenting jaw deformities on malocclusion are evaluated (Figs. 10-12 and 10-13).[51,83-85,87]

The Effects of Respiratory Pattern and Jaw Posture on Maxillofacial Growth

The link between an open mouth or oral breathing pattern and maxillofacial growth has been documented in the literature.[4,5,11,17,24,25,28,31,41,43,45-48,59-66,96,97,105,106,109,110] There has been both animal experimental and human clinical research to support a link between oral respiration, open mouth posture, and the development of maxillomandibular disharmonies. With the use of rhesus monkeys as an experimental model, Harvold and colleagues completely blocked the nares of newborn monkeys.[45-48] The researchers observed consistent facial morphologic changes that gradually occurred with growth in the presence of a constant open mouth and tongue protrusive mandibular posture. The research of this group documented that a constantly open mouth (i.e., clockwise rotation of the mandible) in a growing rhesus monkey was followed by the vertical lengthening of the maxilla. The mandibular inferior border then gradually steepens, with a resulting obtuse gonial angle. Through years of primate laboratory research, Harvold and coworkers confirmed that there are significant correlations between alterations in respiratory patterns (i.e., forced mouth breathing), mandibular (open mouth) posture, tongue protrusion, and characteristic maxillomandibular dysmorphic growth (i.e., long face growth pattern).[45-48]

In human children who have significant nasal obstruction and a resulting open mouth posture, clinical observational studies document a similar downward and backward rotation of the mandible with hypererruption of the maxillary dentition.[59-65] Over several years, the affected children develop what we now recognize as a *long face growth pattern.* This is documented as a vertically long and horizontally retrusive maxillomandibular complex. The term *adenoid facies* was coined to describe the child who presents with a long, narrow, flat face; protruding teeth; and lips that are widely separated at rest. These features are often accompanied by an anterior open-bite malocclusion and lip strain when attempting mouth closure. To better understand the concept, Linder-Aronson and Woodside completed a study in which they analyzed the faces of children with chronic nasal obstruction who were scheduled to undergo tonsillectomies and adenoidectomies at a pediatric hospital in Stockholm, Sweden.[63] They

documented a tendency toward a long lower anterior facial height in this group of children. Interestingly, they found that, after the adenoids were removed and with enough time, there was at least some improvement in the children's facial morphology. Unfortunately, the structure of these long faces did not return to normal. With or without adenoidectomy being carried out during childhood, many of these children reach adolescence with persistent nasal airway obstruction in combination with significant jaw dysmorphology and malocclusion (i.e., the long face growth pattern). It is our recommendation that, by adolescence, all aspects (i.e., airway obstruction, skeletal dysmorphology, and malocclusion) be simultaneously addressed to improve function in the head and neck (e.g., breathing, swallowing, speech, chewing, lip closure) and to enhance facial aesthetics.[83-85]

Simultaneous Management of Chronic Obstructed Nasal Breathing and the Presenting Dentofacial Deformity

Posnick and colleagues conducted a clinical study with the use of the *Nasal Obstruction Symptom Evaluation* (NOSE) survey questionnaire to prospectively assess a consecutive series of patients (N = 43) who reported both chronic nasal obstruction and the presence of a significant dentofacial deformity with malocclusion that involved at least the maxilla.[83] The NOSE questionnaire is considered to be a useful marker of symptomatic nasal airway obstruction.[42,98-101] Each study subject was documented to have septal deviation and inferior turbinate enlargement that were consistent with airway symptoms. Any presenting physical findings of a tight nasal inlet or an elevated nasal floor were not specifically studied but were clinically addressed in each patient, when indicated. Each study patient simultaneously underwent septoplasty, the reduction of the inferior turbinates, and the surgical correction of the presenting jaw deformity that included, at minimum, a Le Fort I osteotomy. Septoplasty and inferior turbinate reduction were performed at the time of Le Fort I osteotomy through exposure provided by the down-fracture. The consecutive series of patients (N = 43) who met the inclusion criteria were given the NOSE survey questionnaire before they underwent surgery. The NOSE questionnaire was completed in each patient 3 months after surgery and again at least 6 months after surgery.

The study group included 16 males and 27 females with a mean age of 25 years (range, 15 to 55 years). All patients were treated with a comprehensive orthodontic and orthognathic surgical approach that included a Le Fort I osteotomy as part of the surgical correction. The most frequent pattern of jaw deformity identified in the study group was a long face growth pattern (i.e., maxillary vertical excess with Class II malocclusion), which was seen in 17 out of 43 patients (40%). Simultaneous maxillofacial procedures completed in addition to the Le Fort I osteotomy, septoplasty, and inferior turbinate reduction varied. Twenty-nine of the 43 patients (67%) underwent segmentation of the maxilla to widen the arch width or to correct the curve of Spee. Forty-two of the patients (98%) underwent simultaneous sagittal split ramus osteotomies, 16 (37%) underwent the simultaneous removal of the third molars, and 7 (16%) also underwent suction-assisted lipectomy of the neck. Thirty-seven patients (86%) underwent oblique osteotomy of the chin with reshaping (i.e., osseous genioplasty).

The mean weighted NOSE score before surgery was 63.7. At the 3-month postoperative interval, the mean NOSE score had dropped to 6.9. On the basis of the nonparametric Wilcoxon signed-rank test, this is a significant finding ($P < .001$). The mean NOSE score at 6 months after surgery dropped even further to 6.3. This improvement in nasal breathing remained both clinically and statistically significant as compared with what was found before surgery. The findings confirmed an improved nasal airway by 3 months after surgery among patients who had undergone combined septoplasty, inferior turbinate reduction, and Le Fort I osteotomy; these improvements continued and were maintained at 6 months. All study patients experienced improvements in nasal breathing as a result of the combination of procedures that were carried out.

The incidence of complications that resulted from the intranasal procedures performed simultaneously with the Le Fort I osteotomy as reported by Posnick and colleagues was minimal and not greater than those reported in the literature for isolated procedures. Posnick and colleagues also reported about the incidence of Le Fort I osteotomy–specific complications in the same cohort. The complications were few and not greater than those reported when a Le Fort I osteotomy was carried out as an isolated procedure.

Approaching the Nasal Airway Through Le Fort I Down-Fracture (Video 1 and 2)

A Le Fort I osteotomy provides excellent access to the nasal septum, the inferior turbinates, the pyriform rims, the nasal floor, the anterior nasal spine, the maxillary sinus cavities, and the ostium, thereby allowing for the correction of any presenting nasal airway obstruction or maxillary sinus pathology at the time of down-fracture (see Figs. 10-9, 10-10, and 10-11).[82,83] Interestingly, most otolaryngologists/head and neck surgeons are not used to viewing these structures from this perspective (i.e., through the down-fracture), whereas orthognathic surgeons are. There are several technical details to consider when completing septoplasty or inferior turbinate reduction through the exposure provided by the Le Fort I osteotomy. As always, care is taken to maintain the integrity of the nasal mucosa when down-fracturing the maxilla. Nevertheless, tears in the mucosa are common. After the down-fracture and disimpaction of the maxilla, an elevator is used to achieve the submucosal exposure of all

buckled and deviated portions of the cartilaginous and bony septum. With the use of a rongeur, the buckled or deviated portions of the cartilaginous and bony septum are removed (i.e., submucosal resection); however, adequate dorsal and caudal components of the cartilaginous septum are preserved for structural support. If a cosmetic rhinoplasty is a future consideration, then the preservation of as much useful septal cartilage as possible for later tip grafting is important. Next, an incision that is parallel and just below each inferior turbinate is completed through the nasal mucosa. If the nasal mucosa was torn during the down-fracture, then the exposure provided is used and extended as needed for the additional visualization of each inferior turbinate. With the use of a scissors (e.g., Mayo scissors), the inferior aspect of each enlarged inferior turbinate can be excised via partial resection. Other surgical techniques to reduce enlarged inferior turbinates are described, such as intramural ablation. The direct visualization of the more cephalic positioned nasotracheal tube within the surgical field limits the chance of injury during the turbinate reduction procedure. There is sufficient room for the surgeon to work around the endotracheal tube. With no oxygen leaks in the ventilation system, the cauterization of the exposed raw surface of each inferior turbinate is completed. Suture repair of the nasal floor mucosa is then accomplished. No nasal packs or splints are required for postoperative management. With this approach, the author has not experienced significant intraoperative bleeding or postoperative airway compromise.

Management of Residual Postoperative Nasal Obstruction

When the baseline presurgical nasal airway obstruction is clarified and then managed simultaneously through the Le Fort I down-fracture, residual nasal obstruction is uncommon. When a degree of postsurgical nasal obstruction persists, it is generally the result of an incomplete presurgical diagnosis or the inadequate operative correction of all of the aspects that are causing the blockage (e.g., constricted aperture, elevated floor, enlarged inferior turbinates, septal deviations). After septoplasty and inferior turbinate procedures and after routine postoperative intranasal swelling subsides, continued nasal obstruction may also occur as a result of scar formation.[67,79,83] Should a degree of nasal obstruction persist, it is important to confirm that residual septal deviation, turbinate hypertrophy, and nasal valve (internal and external) stenosis are not factors. If these causes are ruled out and if postsurgical obstruction remains, scar bands of varied thickness are likely to be the cause. If so, the intranasal synechiae can extend from the operated septum to the inferior turbinates or to the healing areas along the nasal mucosal floor. The resulting scar bands are usually small to moderate in size, and they can often be corrected in the surgeon's office with the use of local spray anesthesia and scissors transaction under endoscopic visualization. Occasionally, dense, thick synechiae occur; these may contract a straightened septum into a lateralized position. For more extensive scar bands and when further septoplasty or turbinate reduction is required, management in the operating room via an intranasal approach (with the placement of a separating splint between the septum and the lateral nose to prevent the adjacent fresh mucosal edges from re-creating the scar contracture) is preferred.

Effects of Maxillary Arch Expansion and Nasal Floor Recontouring on the Airway

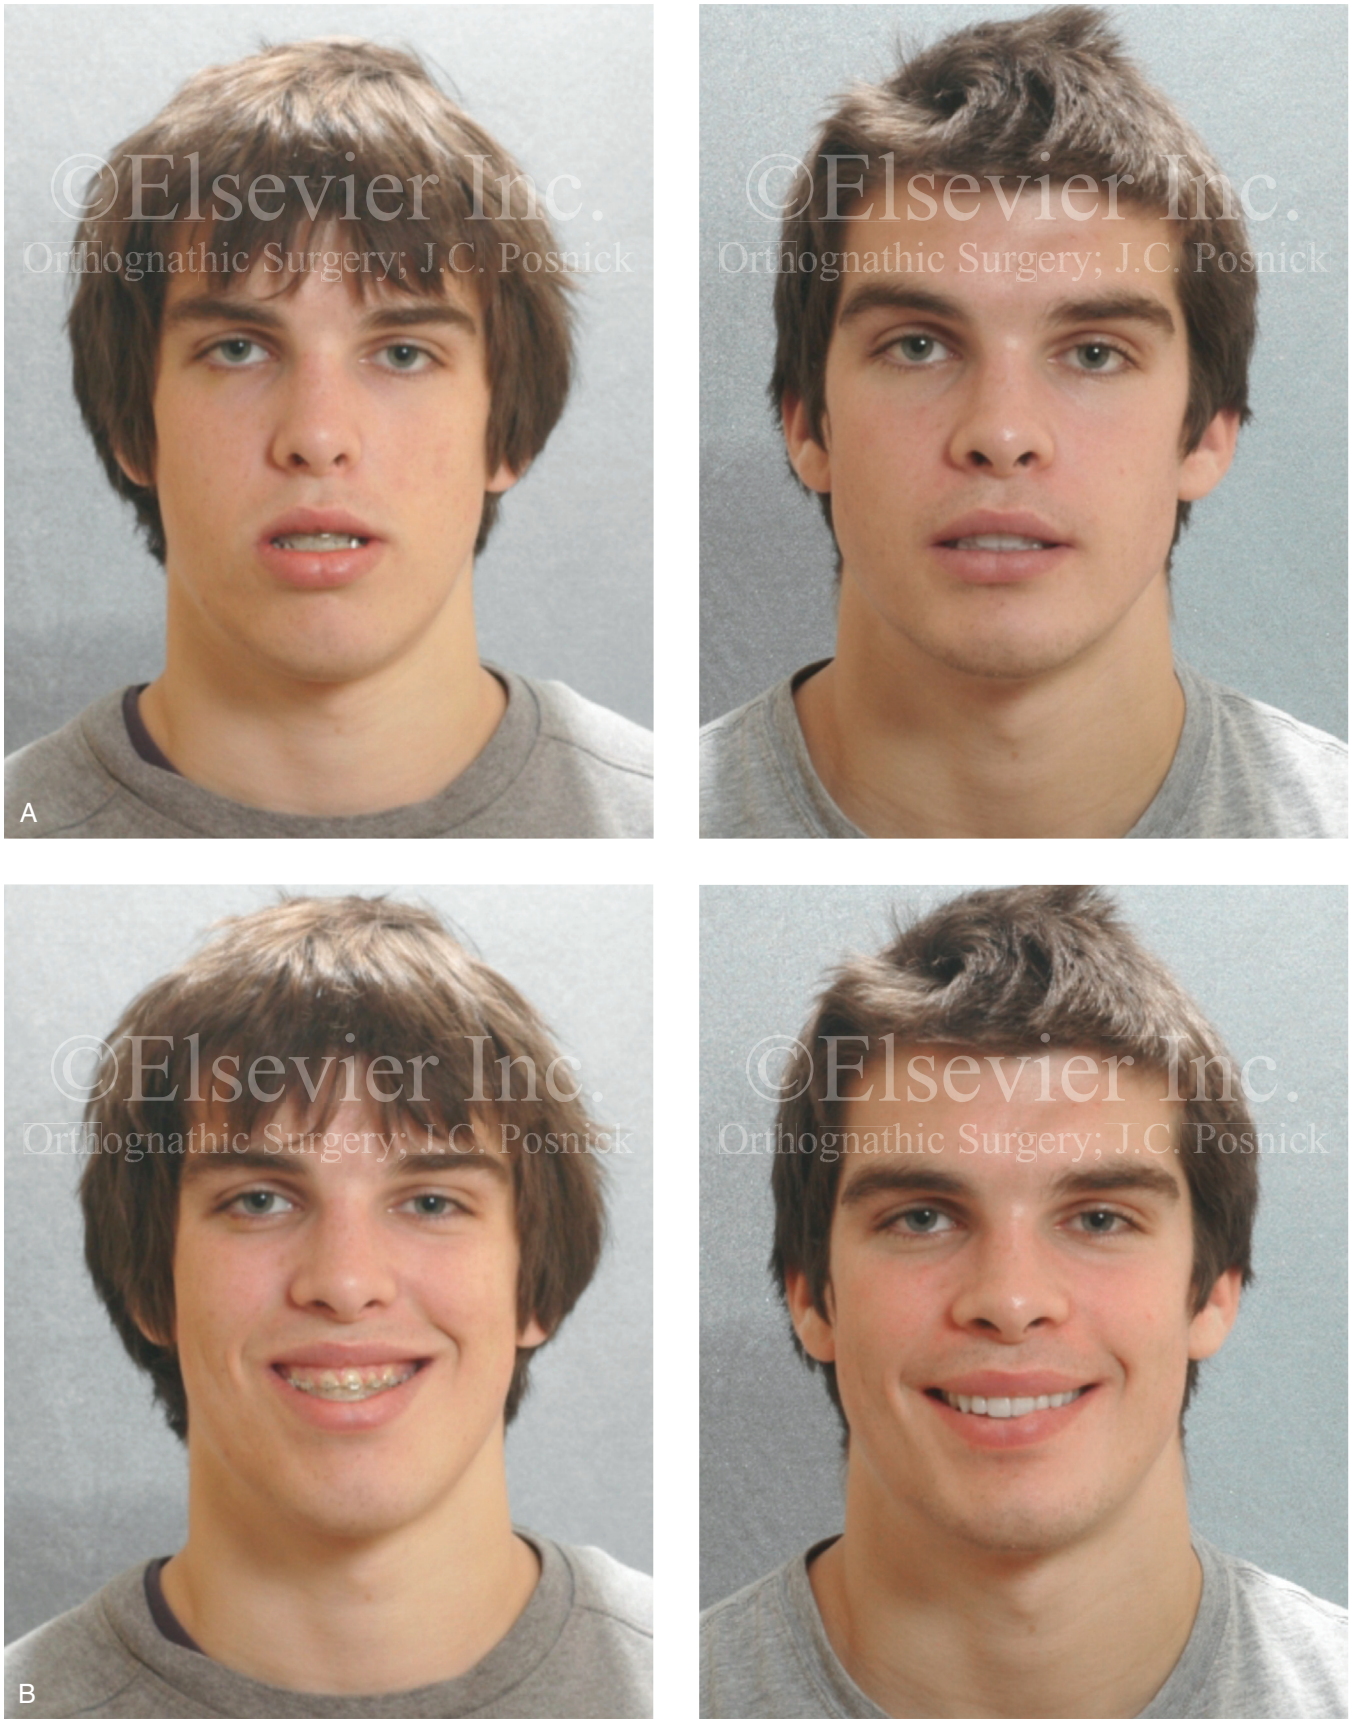
Nasal Floor Recontouring: Effects on the Airway (Video 3 and 4)

The presence of excess vertical alveolar height of the anterior maxilla above the roots of the teeth results in a *high nasal floor* that constricts the nasal passageways, thereby causing increased nasal airway resistance.[24,113] This is a frequent occurrence in patients with a long face growth pattern (see Chapter 21). The need for vertical intrusion (i.e., superior repositioning) of the anterior maxilla to reduce the gummy smile, to improve lip closure, and to reduce mentalis strain is generally required as part of the long face correction (see Figs. 10-5, 10-11, and 10-13). As a result of maxillary intrusion, any baseline nasal obstruction caused by a high nasal floor will worsen unless it is simultaneously addressed. The *need to recontour the nasal floor, the pyriform rims, and the anterior nasal spine region* is also frequent in patients with cleft lips and palates (e.g., unilateral or bilateral cleft lip and palate) that present with a maxillary deformity. *Recontouring to lower and level the nasal floor, to widen the pyriform rims, and to reduce and reshape the anterior nasal spine* can simultaneously be performed through the Le Fort I down-fracture. This will both enhance upper lip and nose aesthetics and reduce nasal airway resistance. The recontouring procedure is carried out with a watermelon-shaped bur on a low-speed rotary drill and a rongeur under direct visualization either before or after the maxilla is secured (i.e., fixed with plates and screws) in its new location (see Chapter 15 and Fig. 10-11).

Maxillary Arch Expansion: Effects on the Airway

Studies predominantly show that *maxillary arch expansion* will improve a *tight nasal inlet* and thereby decrease nasal airway resistance.[15,22,68] The documented improved nasal breathing is believed to result from a widened airway space, primarily at the level of the *internal nasal valve* brought about by maxillary arch expansion.* Seeberger and colleagues[92] and Wreidt and colleagues[114] examined patients via acoustic rhinometry before and after surgically assisted rapid maxillary expansion and recorded profound increases in total nasal volumes. They also reported that their patients experience better nasal airflow with a distinct subjective

*References 6, 9, 16, 22, 26, 34, 39, 40, 44, 49, 62, 68, 69, 102, 108, 111



• **Figure 10-12** A 20-year-old man with a combined long face growth pattern (environmental) and a right side hemimandibular elongation (hereditary). There is an asymmetrical Class III negative overjet malocclusion. The patient had a lifelong history of obstructed nasal breathing with documented septal deviation, hypertrophic inferior turbinates, and an elevated nasal floor. He was referred to this surgeon for evaluation, and he agreed to a comprehensive orthodontic and orthognathic approach. With the relief of dental compensation, the patient's surgery included a maxillary Le Fort I osteotomy (horizontal advancement and vertical shortening); bilateral sagittal split ramus osteotomies (mandibular straightening and asymmetrical correction); osseous genioplasty (vertical shortening); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

improvement in nasal breathing. Maxillary widening may be accomplished with a number of techniques (e.g., rapid palatal expansion, surgically assisted rapid palatal expansion, segmental Le Fort I osteotomy). The method selected is dependent on the age of the patient and the combination of airway, occlusal, and facial aesthetic needs. The frequent need for arch expansion in the individual with a long face growth pattern is well recognized (see Fig. 10-4), and it is also common with other dentofacial deformities (e.g., maxillary deficiency with relative mandibular excess, primary mandibular deficiency, bimaxillary dental protrusion, and cleft maxillary deformities). Expiratory pressure, expiratory flow values, and inspiratory flow values have all been documented to improve immediately after lateral nasal wall widening. These benefits should remain long term unless lateral wall relapse occurs.

Comprehensive Approach to Chronic Nasal Airway Obstruction

The fact that Posnick and colleagues showed a more significant symptomatic improvement in nasal breathing in their study patients as compared with that found by Stewart and colleagues when septoplasty only was carried out is not surprising.[100] This likely resulted from the strict patient selection process and the other procedures that were simultaneously carried out (e.g., inferior turbinate reduction, transverse widening of the maxilla, horizontal maxillary advancement, lowering the nasal floor by recontouring).

An interesting observation emerged from the COG-ENT chronic rhinosinusitis study that was completed in 2001.[98-101] The COG-ENT researchers found that patients who were undergoing functional endoscopic sinus surgery in combination with septoplasty and inferior turbinate reduction showed even greater clinical improvement in nasal breathing as compared with those undergoing functional endoscopic sinus surgery alone. This confirms the added value to the airway (i.e., the improved breathing) related to carefully selected diagnosis-driven procedures being simultaneously carried out.[19,35,50,54,70,72,78]

Conclusions

Orthognathic surgeons have the opportunity to improve disease-specific quality-of-life issues for their patients at the time of Le Fort I osteotomy by performing diagnosis-driven intranasal procedures in those with symptomatic chronic nasal airway obstruction and sinus drainage difficulties. The improvement of nasal airflow often enhances the patient's sense of smell, sinus drainage, sleep comfort, daytime alertness, dental health, and ability to perform exercise. Ignoring any baseline nasal floor and pyriform rim skeletal deformities at the time of orthognathic surgery is also likely to result in suboptimal facial aesthetics.

Case Presentation

A classic example of the combined occurrence of chronic nasal airway obstruction and dentofacial deformity is seen in the description of a 15-year-old high school student who arrived for evaluation accompanied by her parents (see Fig. 10-13).

Since early childhood, the patient had a forced mouth-breathing pattern, and snoring at night was documented. With exercise, she had difficulty getting enough air through the nose. She was seen by an otolaryngologist/head and neck surgeon and found to have a deviated nasal septum, a hypertrophic inferior turbinate, and a tight nasal aperture. However, no treatment was carried out earlier during her life. As a teenager, she presented with a long face growth pattern, an anterior open bite, and a Class II excess overjet

• **Figure 10-13** A teenage girl with a long face growth pattern is treated with a comprehensive orthodontic and surgical approach. After orthodontic (dental) decompensation, her surgical procedures included a maxillary Le Fort I osteotomy in segments (vertical intrusion, horizontal advancement, and arch expansion) bilateral sagittal split osteotomies of the mandible (horizontal advancement and counterclockwise rotation); oblique osteotomy of the chin (vertical shortening and horizontal advancement); and septoplasty, inferior turbinate reduction, and recontouring of the nasal floor. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

Pre surgery

After treatment

• **Figure 10-13, cont'd C,** Oblique facial views before and after treatment. **D,** Profile views before and after treatment. **E,** Occlusal views with orthodontics in progress and then after surgery.

malocclusion. There were also concerns about a gummy smile, difficulty maintaining lip closure, speech articulation errors, and a weak profile.

Both orthodontic and surgical consultation recommended a comprehensive approach as the most biologic way to improve the upper airway obstruction; to improve the occlusion and the long-term dental health; to improve lip closure; and to enhance facial aesthetics. Orthodontic treatment was initiated to relieve dental compensation, and jaw and intranasal surgery followed.

Management of Dentofacial Deformity Required the Following:

- Maxillary Le Fort I osteotomy in three segments
- Bilateral sagittal split ramus osteotomies of the mandible
- Oblique osteotomy of the chin

Management of Chronic Nasal Airway Obstruction Required the Following:

- Submucous resection of deflected and buckled portions of the nasal septum
- Reduction of the hypertrophic inferior turbinates
- Maxillary transverse expansion (Le Fort I osteotomy in segments) with nasal aperture widening
- Recontouring (lowering) of the nasal floor and the anterior nasal spine

The patient is shown before and 1 year after surgery and the completion of orthodontic treatment.

Use of Deliberate Hypotensive Anesthesia to Limit Blood Loss

Historical Perspective

Deliberate hypotensive anesthesia (DHA) to provide a less bloody field and better operative conditions was first proposed by Harvey Cushing in 1917 for neurosurgical procedures.[58] Since then, a spectrum of pharmacologic agents (e.g., nitroglycerine, calcium-channel blocking agents, short-acting beta-adrenergic blockers, purine compounds) and techniques have been used in a variety of combinations in an attempt to accomplish the same objectives.*

In 1950, Enderby and colleagues demonstrated the value of DHA to reduce blood loss in a series of 35 patients.[78-81] Eighteen of the 35 (51%) were judged to have an excellent reduction in blood loss during deliberate hypotension, and 8 of the 35 (23%) were judged to have a moderate reduction. The authors attributed this inconsistent effectiveness to individual vascular responses to the hypotensive drugs that were used. They surmised that bleeding at the surgical site could be further minimized if the wound itself was kept uppermost (rather than dependent) through the use of operating room table positioning (e.g., reverse Trendelenburg position for head and neck procedures). Through special positioning, arterial vessels in the operative field would have less pressure, veins would drain more easily, and thus bleeding at the surgical site should be less.

One of the earliest studies to quantify reductions in blood loss with DHA was performed by Eckenhoff and Rich, who completed research in patients who were undergoing a variety of operations, including rhinoplasty,

*References 5, 8, 20, 26, 33, 36, 40, 54, 55, 63, 65, 67, 82, 88, 89, 98, 99, 111, 116, 119, 128, 150, 151, 155, 160, 166, 168, 178, 181, 182, 190, 191, 196-198, 209, 219, 221, 224, 237, 241-244, 258, 265, 270, 272.

portacaval shunt, and craniotomy for aneurysm.[72,73] Half of the patients underwent DHA (n = 115), and the other half (n = 116) went without hypotension. For each of the procedures, blood loss decreased by 50% or more with hypotension techniques. This was the first DHA study to measure blood loss with the use of a control group. By doing so, it greatly added to the power of the research confirming the value of DHA.

Evidence supporting the use of DHA to reduce blood loss has most commonly been found in studies of orthopedic procedures. Thompson and colleagues studied hypotensive anesthesia to reduce blood loss during total hip arthroplasty.[255] The mean arterial pressure (MAP) of the patients (n = 30) was reduced to 50 mm Hg. The techniques used to do this included sodium nitroprusside (n = 12) and high inspired concentrations of halothane (n = 9); a control group of patients (n = 9) was normotensive. Blood loss was 1200 mL for the normotensive control subjects but only 400 mL for both hypotensive groups. No anesthesia-specific complications were seen. In 1979, Eerola and colleagues completed a controlled study of 55 patients who were undergoing total hip arthroplasty.[76] They found that the 38 patients who were given pentolinium tartrate and halothane for DHA had less blood loss. That same year, Vazeery and colleagues studied patients who were undergoing total hip replacement (n = 25). The patients were given sodium nitroprusside to lower arterial blood pressure.[262] They had significantly less blood loss than the control group (n = 25), which was not undergoing deliberate hypotension. The value of DHA to reduce blood loss has also been confirmed for other procedures, including craniotomy, middle-ear surgery, radical cancer operations, and a variety of head and neck surgeries.

Didier and colleagues suggested that the depression of cardiac output correlated better with a dry field than did arterial blood pressure.[66] To determine whether a decrease in MAP or cardiac output was the primary cause of the decreased blood loss, Sivarajan and colleagues studied "healthy" (American Society of Anesthesiologist I) subjects (n = 20) who were undergoing bilateral sagittal split ramus osteotomies of the mandible.[239] Cardiac output decreased 37% with the use of trimethaphan, but it decreased only 27% with sodium nitroprusside. Interestingly, blood loss was similar for both groups, although cardiac output was two times greater with nitroprusside. The authors concluded that blood pressure rather than cardiac output was the primary determinant of how much blood was lost.

Techniques to Induce Deliberate Hypotensive Anesthesia

Currently, the general consensus is that most patients will have less blood loss if the MAP is decreased to 50 mm Hg to 65 mm Hg in the surgical field. It is also believed that patient positioning and attention to ventilation will significantly influence venous return and therefore play important roles in minimizing blood loss. Clinical studies have focused on the use of a variety of specific drugs and combinations of drugs to keep the arterial blood pressure at the surgical site at the level believed to significantly decrease blood loss (i.e., 50 mm Hg to 65 mm Hg).

Body positioning (e.g., reverse Trendelenburg position for head and neck procedures), the hemodynamic effects of mechanical ventilation (e.g., maintaining normal or low carbon dioxide [CO_2] levels), and changes in the heart rate and the circulatory volume are factors that can be manipulated with drugs to lower blood pressure in the surgical field to the desired level. The effective use of these physiologic maneuvers helps to decrease the dose of potentially toxic drugs that are needed to produce the preferred level of hypotension.

The ideal agents for inducing hypotension should have the following characteristics: 1) ease of administration; 2) a predictable and dose-dependent effect; 3) rapid onset; 4) rapid recovery from effects; 5) quick elimination without the production of toxic metabolites; and 6) minimal effects on blood flow to the vital organs. Many anesthetic and vasoactive drugs have been used successfully in clinical practice to induce DHA for orthognathic procedures. These agents primarily include volatile anesthetics; direct-acting vasodilating drugs; beta-adrenergic receptor–blocking drugs; and combined alpha- and beta-adrenergic receptor–blocking drugs. Examples of such agents include sodium nitroprusside, nitroglycerin, esmolol, and labetalol.

Clearly, one can decrease MAP by increasing the amount of inhaled anesthetics such as sevoflurane, isoflurane, and desflurane. Certain drugs that permit moment-to-moment controlled blood pressure are the most popular. The differences in pharmacologic properties among these agents suggest that combinations of these drugs may provide a better pharmacologic profile than could be provided by any agent used alone.[234]

Effects of Deliberate Hypotensive Anesthesia on Organ Function

DHA decreases arterial blood pressure by decreasing cardiac output, by decreasing systemic vascular resistance, or by decreasing a combination of the two. Cardiac output must remain sufficiently high not only to provide adequate oxygen and energy substrates to vital organ systems but also to remove metabolic waste products before any accumulation can cause tissue damage. The effect of DHA on cardiac output depends on the balance of its effects on preload, afterload, myocardial contractility, and heart rate. Homeostatic mechanisms also come into play. Other important factors include the physical condition of the specific patient, the anesthesiologist's administration of additional drugs, and the pattern of ventilation used intraoperatively. The constant assessment of the patient's intravascular fluid volume throughout surgery is also required to ensure optimal vital organ function.

Inadequate oxygen supply to the brain and myocardium as a result of inadequate tissue blood flow or perfusion

pressure is the principal hazard of DHA, particularly with regard to the effects on cerebral metabolic homeostasis.* Studies to date have shown that the responsible use of DHA does not produce permanent changes in cerebral hemodynamics. For example, the cognitive performance of elderly patients on psychological tests given several days after total hip arthroplasty that involved DHA did not differ from their performance before surgery. The current clinical rationale for studying a lower limit for MAP (e.g., 50 mm Hg to 55 mm Hg) in normotensive patients is based on the belief that this range represents the lowest MAP at which autoregulation of the cerebral blood flow is still intact. However, for chronically hypertensive patients or for patients who are older, the curve is thought to shift to the right. In other words, a higher MAP is required in these individuals to maintain autoregulation. The partial pressure of carbon dioxide in the blood ($paCO_2$) is also an important consideration during DHA. This is because cerebral blood flow changes linearly with $paCO_2$. Whether one drug is better than another for preserving cerebral blood flow is debated.

The preservation of cardiac function is essential, but it is known to be altered by DHA techniques.† Interestingly, cardiac function is better preserved with isoflurane than with equal hypotensive doses of halothane. Studies have shown that isoflurane is suitable for healthy patients who are undergoing DHA. Clinical studies also show that the cardiovascular effects of general anesthetic doses of propofol are similar to those of isoflurane. During deliberate hypotension, the maintenance of an oxygen supply that is sufficient for the metabolic needs of the myocardium is of primary importance. As a general rule, patients with known or suspected ischemic heart disease should not undergo DHA.

Renal blood flow normally equals 20% to 25% of cardiac output. Renal circulation is greatly influenced by autoregulatory mechanisms.[61,110,159] Clinical studies suggests that normovolemic patients typically experience the rapid recovery of urine production after the discontinuation of DHA.[255] Thompson and colleagues could find no significant changes in serum creatinine, blood urea nitrogen, or serum or urinary electrolytes for patients (n = 30) who had undergone DHA.[255]

Monitoring During Induced Deliberate Hypotensive Anesthesia

Beat-to-beat measurement of arterial blood flow is mandatory for patients who are undergoing clinically significant deliberate decreases in blood pressure. The usual practice is to insert an arterial catheter for the continuous monitoring of blood pressure. Perhaps most importantly, the catheter allows for the intermittent sampling of arterial blood for acid–base status (i.e. metabolic acidosis). It also allows for the confirmation of adequacy of oxygenation and ventilation, and for serial hematocrit measurements. Electrocardiographic monitoring is also essential for detecting signs of inadequate myocardial perfusion or oxygen delivery, such as S-T segment or rhythm changes. The correlation between end tidal CO_2 and $paCO_2$ is considered somewhat unreliable during hypotension. Nevertheless, capnography still provides useful information during DHA. It may also help to avoid hyperventilation and its resultant hypocapnea, which could be harmful; the decrease in $paCO_2$ could further reduce cerebral blood flow during moderate hypotension. Pulse oximetry and temperature monitoring should also be routinely used, and the measurement of urine output is also essential. Serum electrolyte, blood gas, and hematocrit levels should also be measured at intervals.

Complications Associated with Deliberate Hypotensive Anesthesia

The precise incidence of complications with the use of DHA is difficult to determine.[19,75,41,152,179,248,253] Current data regarding non-fatal complications indicate that hypotension of 50 mm Hg to 65 mm Hg is not a risk factor for young healthy patients (American Society of Anesthesiologists [ASA] 1 and 2). Alternatively, for those individuals with underlying organ dysfunction, the use of DHA may put them at increased risk. Thus, all potential candidates should undergo a complete history and physical examination before surgery. The decision to use DHA should not be made without careful preoperative consideration of patient-specific risk factors.

Special Considerations for the Orthognathic Patient

Before beginning an orthognathic procedure, the logistics of patient positioning, the expected length of the surgery, and the confirmation of patient-specific risk factors for DHA should be discussed by the anesthesiologist and the surgeon.[264] Better drugs, more accurate monitoring, a greater level of experience with the techniques, and the consistency of the surgical procedures themselves have permitted a higher percentage of patients to benefit from DHA.* Nevertheless, relative contraindications include a history of cerebrovascular or cardiovascular disease, renal dysfunction, liver dysfunction, peripheral vascular disease, and severe anemia. Fortunately, the orthognathic patient rarely suffers from these dysfunctions. Exceptions include older individuals who are undergoing orthognathic surgery for the treatment of obstructive sleep apnea.[228,261] Given current demographics, this is likely to represent an ever-increasing patient population (see Chapter 26).

Use of Hemorrhage Depressors to Limit Blood Loss

Tranexamic Acids

Tranexamic acid is a synthetic amino acid that inhibits fibrinolysis and that has been shown to reduce blood loss and the need for blood transfusion during specific surgical procedures, including total knee arthroplasty, spine surgery, cardiac surgery, and orthognathic surgery.* It has also been used for the treatment of postoperative bleeding in anticoagulated patients after oral surgery (e.g., the extraction of teeth).[32,212] **Senghore and Harris** showed that a single intravenous preoperative dose of tranexamic acid was effective for preventing excessive postoperative bleeding in healthy adult patients who were undergoing third molar extraction.[232]

Choi and colleagues completed a double-blind, randomized, controlled trial to study the effects of tranexamic acid on blood loss during orthognathic surgery.[51] This trial included 73 consecutive patients who were undergoing bimaxillary orthognathic osteotomies. Each study patient received either a bolus of tranexamic acid (20 mg/kg) or a placebo (normal saline) intravenously just before surgery. All patients underwent DHA in accordance with standard hospital protocol. Intraoperative blood loss, operative time, the transfusion of blood products, and perioperative hemoglobin and hematocrit levels were recorded. The total blood loss and the blood loss during the maxillary (Le Fort I) procedure were reduced significantly in the group that received tranexamic acid as compared with the control group. The difference in blood loss during maxillary surgery was 428 mL versus 643 mL. The difference in total blood loss was 878 cc versus 1257 cc. The authors concluded that the use of a preoperative intravenous bolus of tranexamic acid (20 mg/kg) reduces blood loss as compared with a placebo during bimaxillary orthognathic osteotomies.

Desmopressin

Desmopressin acetate is an analog to the naturally occurring hormone vasopressin.[4,114,115,138,147,222,225,245] It enhances the vascular endothelial cell release of a number of compounds, including high multimetric von Willebrand factor, factor 7c, factor 7ag, and tissue-type plasminogen activator. Desmopressin by itself has been suggested to be the factor that is responsible for the increased hemostatic activity seen in patients with liver dysfunction and uremia. Additional observations indicate that desmopressin may improve platelet function.

Both of these hemorrhage depressors—desmopressin and tranexamic acid—have been used in combination with DHA during orthognathic surgery at the University of Göteborg Hospital since 1999. **Zellin and colleagues** retrospectively evaluated and compared the total perioperative blood loss for a group of patients who were assigned to either DHA or a combination of DHA and the use of both of these hemorrhage depressors (i.e., desmopressin and tranexamic acid).[276] Thirty orthognathic patients who were consecutively operated on via a standardized Le Fort I osteotomy were assigned to either the control group (n = 15) or the treatment group (n = 15). Both groups underwent DHA. The treatment group received additional hemorrhagic depressors (i.e., both tranexamic acid and desmopressin). The mean blood loss was 740 cc in the control group and 400 cc in the treatment group. This was a statistically significant reduction in blood loss in the treatment group (1 g tranexamic acid intravenously and 0.3 μg per kilogram of body weight of desmopressin subcutaneously).

Deliberate Hypotensive Anesthesia Used in Orthognathic Surgery: Review of the Literature

Schaberg and colleagues were the first to evaluate blood loss and the human physiologic response with the use of DHA in the form of sodium nitroprusside during orthognathic surgery.[227] They studied a consecutive series of ASA I patients undergoing Le Fort I maxillary osteotomies. Each was placed in reverse Trendelenburg position (10 degrees), and sodium nitroprusside was used to induce hypotension to not less than 80 mm Hg systolic pressure or 60 mm Hg MAP. The mean estimated blood loss was 256 ± 35 mL. No control group was used for comparison.

Washburn described a retrospective series of 58 individuals who underwent maxillofacial procedures (n = 53 orthognathic patients) in which morphine was used to supplement halothane to induce hypotension.[267] The goals were to limit blood loss and to improve the surgical field. There was one death (possibly from halothane-induced liver failure), and only one patient required blood replacement.

Golia and colleagues studied nine patients who underwent either maxillary or combined maxillary and mandibular osteotomies; the DHA techniques that were used included halothane, nitrous oxide, and supplemental doses of muscle relaxants and narcotics.[106] Nitroglycerin was added for the purpose of lowering the MAP during periods with a high potential for increased blood loss (e.g., Le Fort I down-fracture). Estimated blood loss averaged 439 mL and the hemoglobin/hematocrit level fell from 13.8 hemoglobin/41 hematocrit to 12 hemoglobin/36 hematocrit (4.9%). The authors concluded that nitroglycerin was a safe and efficacious agent to help control MAP and blood loss in the surgical field during maxillary and mandibular osteotomies. No control group was used.

McNulty and colleagues completed a study of 12 patients who underwent orthognathic procedures (i.e., Le Fort I osteotomy or sagittal split ramus osteotomy of the

*References 21-23, 27, 28, 39, 41, 42, 59, 71, 77, 85, 120, 122, 125, 126, 129-132, 171, 186, 187, 214, 233, 238, 252, 254, 277.

mandible) under DHA.[169] The anesthesia agents that were used included fentanyl, isoflurane, and bolus doses (i.e., 10 mg to 20 mg) of labetalol to control the blood pressure in an attempt to improve the surgical field and limit blood loss. The authors reported clinical satisfaction with the surgical field and no complications. No control group was used.

Blau and colleagues compared esmolol in 15 patients with sodium nitroprusside in 15 other patients as the primary drugs for DHA to limit blood loss during Le Fort I osteotomy.[31] All study patients were physically rated as ASA I or II. The mean MAP averaged 58 mm Hg to 60 mm Hg, with a target range set at 55 mm Hg to 65 mm Hg. The mean heart rate was maintained at approximately 70 beats/min with esmolol and 100 beats/min with nitroprusside. The surgeons generally rated bleeding as mild to moderate and the surgical field as "drier" with esmolol. The total measured blood loss was less with esmolol (i.e., 436 mL with esmolol versus 895 mL with nitroprusside). The authors found the advantages of esmolol as compared with nitroprusside to include greater control of the blood pressure, the reduction of blood loss, and a drier surgical field.

Precious and colleagues studied 50 orthognathic surgery patients in a prospective, randomized, blocked, stratified, and single-blind fashion.[206] All patients underwent either sagittal split ramus osteotomies of the mandible, Le Fort I osteotomy, or genioplasty. One group of patients (n = 25) received DHA, whereas the other group (n = 25) received anesthesia with no specific attempt to reduce blood pressure during the operation. The surgeon, who was unaware of which group the patient had been assigned to, rated the surgical field every 15 minutes. At the completion of surgery, three different methods were used to estimate or calculate blood loss. The duration of the procedure was recorded from the time of the first incision to the time of the last stitch placement. The estimated blood loss was significantly less when DHA was used. The surgical field was also rated better, but there was no significant difference in the duration of the procedure with or without the use of DHA. The authors concluded that DHA results in both reduced blood loss and improved visibility in the surgical field.

Enlund and colleagues studied 36 patients who were undergoing orthognathic surgery.[84] Each patient was randomly assigned to be either hypotensive (n = 18) or normotensive (n = 18) during surgery. Hypotension was achieved with the use of isoflurane to a MAP of 50 mm Hg to 64 mm Hg. The hypotensive group had significantly less blood loss per minute. Only two of the patients in each group underwent bimaxillary osteotomies. A majority of the patients in each group underwent only mandibular ramus osteotomies. None of the patients in either group required blood replacement.

Dolman and colleagues completed a prospective, randomized, blinded-to-the-surgeon clinical trial of DHA in a consecutive series of orthognathic patients.[69] The purpose of the study was to compare the quality of the surgical field, the blood loss, and the operative time with either hypotensive or normotensive anesthesia during Le Fort I osteotomy. The study patients (n = 23) were randomized into normotensive or hypotensive anesthesia treatment groups. No local anesthesia with a vasoconstrictor was used by the surgeon. In the experimental group, hypotensive anesthesia was maintained with propofol (3 mg/kg/hr), sufentanyl (0.5 mg/kg/hr), and isoflurane (0.5% in 100% oxygen). The quality of the surgical field in both groups was assessed intraoperatively by direct observation and again postoperatively with video imaging. The surgical time was measured on the videotape, and blood loss was measured by volumetric and gravimetric techniques. There was a statistically significant correlation between the surgeon's perception of the quality of the surgical field and the blood pressure. There was a statistically significant reduction in blood loss when using hypotensive anesthesia. However, there was no significant reduction in operative time when using hypotensive anesthesia. The authors concluded that hypotensive anesthesia is a valuable technique for reducing blood loss and improving the quality of the surgical field during Le Fort I osteotomy.

Praveen and colleagues completed a prospective randomized clinical study to assess DHA and blood loss during orthognathic surgery.[204] A total of 53 patients who were undergoing orthognathic surgery were included in the study. The patient ages ranged from 15 to 33 years. They were randomly allocated to have either normotensive anesthesia or to be given DHA. Median blood loss with DHA was 200 mL; under normotensive anesthesia, it was 350 mL. The authors concluded that there was a pronounced reduction in blood loss during orthognathic operations with the patient under DHA as compared with normotensive anesthesia.

Manola and colleagues completed a prospective randomized comparison of three types of pharmacologic agents to induce hypotension during functional endoscopic sinus surgery.[165] The patients were divided into three equal groups in accordance with the agents used: 1) sufentanyl/sevoflurane; 2) remifentanil/propofol; and 3) fentanyl/isoflurane. Evaluation included surgical field rating and measured blood loss. The authors found that the quantity of blood loss and the visibility of the surgical field were improved with the use of either remifentanil and sufentanyl as compared with fentanyl.

Choi and colleagues completed a comparative study to report about the use of three different pharmacologic drugs to induce DHA in patients who were undergoing orthognathic surgery (i.e., Le Fort I and sagittal split ramus osteotomies of the mandible).[49] The 50 adult patients were randomly allocated to receive either nitroglycerin (n = 25) or remifentanil (n = 25). The MAP and the heart rate were measured at intervals. The heart rates and blood pressures were significantly better controlled with the use of remifentanil as compared with nitroglycerin. Interestingly, there were no significant differences in the surgical field ratings or the measured blood loss between the two groups.

Farah and colleagues completed a comparative study to report on the use of two different pharmacologic protocols to induce DHA in patients submitted to orthognathic surgery.[90] Twenty ASA 1 patients between the ages of 17 and 44 years were randomly assigned into two groups: group 1 (clonidine and remifentanil) and group 2 (dexmedetomidine and isoflurane). Other drugs that were used as part of the anesthesia regimen were common to both groups. Specific patient parameters were assessed, including arterial blood pressure; heart rate; temperature during the intraoperative and postoperative periods; incidence of nausea and vomiting; postoperative pain; awakening time; extubation time; and postanesthesia recovery time. The results of the study showed that there were no significant differences between the two groups with respect to physiologic responses or surgical time. Both study protocols proved to be effective and safe. Each was suggested as a satisfactory option to achieve DHA during orthognathic procedures when there is an expectation of significant blood loss.

To review, the literature confirms that DHA is effective for decreasing blood loss and providing better visibility in the surgical field during orthognathic procedures. There are many available drugs and techniques that have been used successfully to lower arterial blood pressure to accomplish these goals. The mechanisms of action of available drugs differ and produce complex changes in reflexes and subsequently the blood flow to various organs. For the healthy young patient, complications are rare. The anesthesiologist and the surgeon must assess each patient carefully and consider the potential risks and complications as well as the benefits before using DHA techniques during orthognathic surgery.

The Need for Blood Replacement in Orthognathic Surgery

Background

For individuals who are undergoing complex orthognathic surgery (i.e., Le Fort I and sagittal split ramus osteotomies of the mandible)—often in combination with other simultaneous procedures (e.g., genioplasty, liposuction, septoplasty, inferior turbinate reduction, removal of wisdom teeth)—a preoperative doctor–patient discussion of the need for intraoperative blood replacement is not just an academic issue.[92,103,107,149,163,201] Published studies indicate that individuals who are undergoing bimaxillary surgery require blood replacement in the range of 2.5% to 75%.[15,64,138,142,148,156,200,218,223,226,235,259,274] Rummasak and colleagues retrospectively studied patients who underwent bimaxillary osteotomies (n = 208) during a 4-year timeframe from 2005 to 2009 at a single institution. The authors reviewed possible factors for intraoperative blood loss and looked for statistical significance. They documented that, with consistent anesthesia techniques, the two factors of greatest importance for blood loss were 1) the experience of the surgeon and 2) the overall operative time.[223]

Madsen and colleagues conducted a prospective study to evaluate the predictive value of the viscoelastic properties of whole blood samples collected preoperatively in relation to intraoperative blood loss in patients who were undergoing orthognathic surgery (n = 41). They concluded that, with other variables controlled for, the etiology of intraoperative bleeding can be predicted by means of preoperative thromboelastography. This is a global method that addresses the complex interplay among coagulation factors, blood platelets, and components of the fibrinolytic system. Blood platelet count, activated partial thromboplastin time, prothrombin time, plasma fibrinogen concentration, and D-dimer concentration were determined by routine methods. The authors conclude that thromboelastography results in individual patients can be used for the evaluation of bleeding risk. Further studies will be required to confirm the validity of their findings.[162]

Methods to limit the need for blood replacement continue to evolve and include refinements in DHA techniques as well as in surgical management (i.e., patient selection, collaborative clinical efforts, and the efficiency of the operation and the postoperative care).[102] Despite stringent donor screening criteria and the rigorous testing of every unit of blood, there remains a risk for the transmission of several pathogens.[70,93,104,108,134,177] For viruses such as the human immunodeficiency virus (1 in 2,135,000), hepatitis B virus (1 in 205,000), and hepatitis C virus (1 in 2,000,000), this is due mainly to "window-period" donations.[34,247] The risks of newly emerging pathogens that can affect blood safety (e.g., Creutzfeldt-Jakob disease) remain unclear. There are other pathogens (e.g., cytomegalovirus, parvovirus B19) that are common in the general donor population and that may pose a risk in the immunosuppressed patient.[213] In addition, allogenic transfusion has been shown quantitatively to be an important contributor to postoperative infection.[94,260]

The options of autogenous and donor-directed blood banking and their popularity for elective surgery are attributed to their perceived safety, to refinements in blood bank administration, and to public concern about the hazards of allogenic blood replacement.[16,86,91,105,118,167,184,210,240] In at least one state (California) and one nation (Germany), the preoperative discussion of blood replacement options is mandated by law and must be documented in the medical record. Other alternatives to allogenic transfusion include acute normovolemic hemodilution, intraoperative blood salvage, and perioperative therapy with recombinant human erythropoietin (Procrit).[35,101,136,170,173,180,230,231]

The absolute need for and actual use of blood transfusion in the practice of orthognathic surgery remains dependent on considerations that relate to total whole body oxygen delivery and its ability to meet the body's metabolic needs.[56,121,175,189] Many individual hospitals have instituted strict criteria for the transfusion of blood products.[215] Although mandated criteria may decrease the use of blood transfusions, it remains unclear if complications or delays in recovery have occurred as a result.[250]

Review of Study

Posnick and colleagues completed a retrospective study to review blood replacement practices in a consecutive series of a single surgeon's experience with patients who all underwent, at a minimum, simultaneous Le Fort I maxillary osteotomy, bilateral sagittal split ramus osteotomies of the mandible, septoplasty, and inferior turbinate reduction procedures.[202] Many patients also underwent additional adjunctive procedures.

A chart review of a consecutive series of the surgeon's patients (n = 34) who underwent elective bimaxillary orthognathic surgery (Le Fort I osteotomy and sagittal split osteotomies of the mandible) in combination with intranasal (septoplasty and inferior turbinate reduction) and often other simultaneous procedures during a 5-month time frame at a single institution was carried out (see Table 11-1). The chart review occurred at least 3 months after surgery for all patients.

Each patient was also evaluated for complications specific to the procedures that were carried out. Potential complications specific to the orthognathic procedures included infection that required the extended use of antibiotics or drainage procedures; dental injury; fibrous union; aseptic necrosis; bleeding that required secondary treatment; and oroantral, oronasal, and orocutaneous fistulas. Potential complications specific to the intranasal procedures included postoperative nasal bleeding that required packing or cauterization; the need for postoperative blood transfusion specific to nasal bleeding; the presence of septal perforation; and postoperative nasal obstruction that required additional procedures within 3 months after orthognathic surgery. Potential perioperative airway compromise was also reviewed, including the need for delayed extubation, reintubation, or tracheotomy. Potential complications specific to transfusions, including infections and autoimmune reactions, were also sought. The patient records that were reviewed included the office chart; the hospital records; and the data stored at the Red Cross (hospital) blood bank. Specific study data collected for each patient (n = 34) can be found in Table 11-1.

The study group included 15 male patients and 19 female patients. The mean age was 22 years and ranged from 13 to 65 years; the median age was 22 years. Thirteen of the 34 patients were less than 18 years old. All patients were treated with a combined orthodontic and surgical (orthognathic and intranasal) approach. The most frequent pattern of jaw deformity that was identified for the study group was asymmetric mandibular excess in 9 out of 34 patients (26%); this was followed by a cleft-craniofacial syndrome being found in 7 out of 34 patients (21%) and a long face growth pattern in 7 out of 34 patients (21%). Additional simultaneous facial procedures that were completed varied. Forty-four percent of the patients (15 out of 34) underwent the simultaneous removal of wisdom teeth. Twenty-one percent of the patients (7 out of 34) also underwent suction-assisted lipectomy of the neck. Eighty-eight percent of the patients (30 out of 34) underwent an osseous genioplasty. Eighteen percent of the patients (6 out of 34) underwent iliac (hip) bone grafting. Fifty-nine percent of the patients (20 out of 34) underwent maxillary (Le Fort I) segmentation. Six percent of the patient (2 out of 34) underwent otoplasty. For all patients, the intranasal procedures included both septoplasty (submucosal resection) and inferior turbinate reduction.

All patients were either extubated in the operating room or within the first hour after surgery while in the recovery room. No patients required overnight intubation, reintubation, or tracheotomy. With respect to complications, no patients required nasal packing or postdischarge blood transfusion. No patient required a return to the operating room for the control of bleeding or airway management.

Twenty-six of the 34 study patients (76%) elected to auto-donate (bank) blood in advance of their surgeries. Two of the 34 study patients auto-donated two units of blood, whereas 24 of the 34 auto-donated just one unit. Only one of the 26 patients that auto-donated received back her banked blood (1 out of 34 or 3% of study patients); she received just one unit of autogenous blood. One of the 34 study patients received a cross-matched anonymously donated (i.e. allogenic) unit (1 out of 34 or 3%). This patient did not elect to auto-donate blood in advance of surgery, and she received just the one unit of blood. Actual autogenous blood use within the group that banked blood was assessed to determine the proportion of discarded stored units. On the basis of the total units of blood that were pre-donated, 28 out of 29 (97%) of the stored units were not used and therefore discarded.

The records of each study patient (n = 34) were specifically reviewed for possible complications associated with the harvesting of autogenous blood and receiving a blood transfusion. Neither of the two patients who received packed red blood cells (one autogenous and the other homologous) experienced intraoperative or postoperative cardiovascular or respiratory compromise. There was no evidence of an adverse event such as an allergic reaction, a transfusion-related infection, hemolysis related to incompatible blood type, or an alteration of the immune system in either patient. According to a review of the blood bank records and discussions with the patients and their families, no complications were known to have occurred as a result of the blood-harvesting process.

Controversies in Blood Replacement for Orthognathic Surgery

Autogenous blood transfusion is the collection and then transfusion of a patient's own blood. Allogenic blood is collected from someone other than the patient. During recent years, insights into the use of autogenous blood led to a complete revision of the National Heart, Lung and Blood Institute's recommendations regarding the use of autogenous blood. Despite the reduction of the risk of transmitting viruses such as human immunodeficiency

virus, hepatitis B virus, or hepatitis C virus, the transfusion of autogenous blood remains safer than that of allogenic blood, and it is considered appropriate for properly selected patients. However, there is still a risk of adverse reactions, bacterial contamination, and errors in the identification of the units. Directed donations (i.e., blood donations from a friend or family member) for a designated patient are not as safe as the patient's own blood and must not be considered equivalent to an autogenous blood transfusion.

If transfusion is likely for a planned surgical procedure, there are several theoretical ways of obtaining autogenous blood, including 1) preoperative autogenous blood donation; 2) intraoperative blood salvage; and 3) acute normo-volemic hemodilution. In general, autogenous (intraoperative) blood collection techniques are considered undesirable for orthognathic surgery as a result of the associated saliva contamination. Acute normo-volemic hemodilution is the removal of blood and the simultaneous infusion of cell-free solutions to maintain intravascular volume before surgical blood loss. The removed blood is transfused during or after surgery, as needed, to maintain the desired hemoglobin levels. The use of this technique requires significant clinical expertise because of its associated physiologic consequences, and there is increased risk with DHA during orthognathic surgery.

The current recommendation of the National Heart, Lung and Blood Institute's conference report is that autogenous blood donations are indicated for patients who are having surgical procedures for which blood is usually crossmatched.[185] The less likely the transfusion for a specific

procedure, the more likely that donated blood will not be used. The recommendations are that patients should not be encouraged to donate blood for autogenous use during surgery unless there is a greater than 10% likelihood that they will need it. The historic literature indicates a wide range (i.e., 2.5% to 75%) with regard to the use of transfusion during bimaxillary orthognathic surgery. The review study performed by Posnick and colleagues indicated only a 6% need.[202] In current practice, the need for blood replacement during bimaxillary orthognathic surgery may be closer to 2%. The high-risk individual (e.g., an adult with obstructive sleep apnea and other comorbidities) can usually be recognized from the outset, and preparations can be made in advance (i.e., blood typing and cross-matching).

Unfortunately, it is not possible to give a quantitative answer to the question, *"When should autogenous or allogenic blood be transfused?"* Practical guidelines have been based on hemoglobin levels, but the inadequacy of this parameter is well known. In general, transfusions should be strongly considered when the patient's hemoglobin level is at 7.0 g per liter (hematocrit = 21) or less. However, in the majority of cases, orthognathic surgery is carried out in young, healthy patients who are free of systemic disease. Thus, there is no absolute hemoglobin level that should automatically trigger a transfusion. A transfusion should be given only on the basis of sound clinical judgment.

Another common question is, *"Should the indications for the use of autogenous blood transfusion differ from those for the use of allogenic blood transfusion?"* If precise indications for a blood transfusion could be defined, autogenous blood would not be given more frequently than allogenic. Although the benefits of allogenic and autogenous blood transfusions are the same, the risks are not. Therefore, the risk-to-benefit ratio clearly supports the more liberal use of autogenous blood. It has been documented that patients who preoperatively donate blood are more likely to be transfused earlier and more frequently than patients who do not auto-donate. Studies have challenged the use of autologous blood donations for elective surgery, because there is the possibility of blood overcollection, the wasting of autologous units, and the costs of preparation and storage. Cohen developed an interesting mathematical model to analyze the use of preoperative autogenous blood donation.[53] The model clarifies how clinicians can customize autogenous blood collection for individual patients to minimize waste (i.e., the need to discard non-transfused blood).

A limited survey of hospitals in the United States determined that the fee generated by the blood bank for each unit of autologous blood that is harvested is estimated to be $255. This includes the storage and delivery of the blood to the operating room or for the disposal of the blood product (i.e., hazardous waste) if it is not used. This fee is typically paid in full by the patient's medical insurance carrier. If the operative procedure for which the blood is donated is not covered by the patient's medical insurance carrier, then the patient is expected to pay the fee.

A critical review of the literature and the evaluation of current clinical practice indicates that, with the effective use of DHA techniques, only a small percentage of individuals who are undergoing even complex orthognathic and intranasal surgery should require blood replacement. Close collaboration between the surgical and anesthesia teams and the recovery of patients in a safely monitored environment will continue to improve operating room and postoperative safety and to reduce blood loss and the need for transfusion in the orthognathic patient.

Perioperative Airway Management in the Patient with a Dentofacial Deformity

A basic airway decision for the surgeon and the anesthesiologist to make for the individual who is to undergo orthognathic surgery and who therefore requires general anesthesia is whether to use induced anesthesia and then directly intubate with or without the use of a Glide Scope (Bell Medical Inc., St. Louis, MO); to use awake fiber-optic intubation; or to use a percutaneous technique (e.g., cricothyroidotomy and tracheostomy). The patient with a dentofacial deformity who presents for general anesthesia should be considered to have a difficult airway until it is proven otherwise (Fig. 11-1).[45,48,123,127,141,146,172,203,207,217]

Head and Neck Examination

The head and neck examination of a patient who is scheduled to undergo endotracheal intubation should include his or her mouth-opening ability; the ability to protrude the lower jaw; any limitations of neck extension; the measurement of the thyromental distance; and the Mallampati test.[140,164,165] These parameters cover the standard reference points to determine whether or not to expect a difficult airway. These parameters represent components of the basic head and neck airway evaluation recommended in the guidelines of the American Society of Anesthesiologists.[6]

1. *Mouth-opening ability.* This is measured as the interincisor distance. A value of less than 4 cm has been proposed as an indicator of possible difficult intubation. Fibrous or bony temporomandibular joint ankylosis will absolutely diminish mouth opening. Muscle spasms or pain may also limit mouth opening, but these factors can be overcome with muscle relaxants and analgesics.
2. *The inability of the individual to protrude the lower jaw forward.* When the mandibular incisors cannot protrude in front of the maxillary incisors, this is considered to be an indicator of a difficult intubation. It is often an indirect test for mandibular retrognathia. In addition, it can be a deceiving indicator of normal jaw morphology in the individual with a normal mandible but with maxillary deficiency.
3. *Limited neck extension.* An angle of less than 20 degrees as measured between the occlusal surface of the maxillary teeth and the neck when it is in full extension is felt to be suggestive of a difficult direct laryngoscopy. A

• **Figure 11-1** Perioperative risk to the airway and its management should be considered during all phases of orthognathic surgery, including before nasotracheal intubation, during surgery, at the time of extubation, and soon after extubation. Individuals who are scheduled for orthognathic surgery who have been recognized to be at high risk for airway compromise should be discussed in advance with the anesthesia team to arrange for special needs. Three patient examples in which these issues came into play are shown: an adult with Noonan syndrome; a teenage girl with Treacher Collins syndrome; and a teenager with the Klippel–Feil anomaly. Each of these patients also has the potential for cervical spine anomalies with limited neck range of motion. The Risk of spinal cord injury should also be evaluated before orthognathic surgery.

percentage of dentofacial deformity patients will have cervical spine anomalies that prevent adequate and safe neck extension.

4. *The Mallampati test.* The visibility of the pharyngeal structures when the mouth is wide open is considered to be of limited use as an individual assessment. However, when this is considered in combination with other physical findings, it is of some value. The dentofacial deformity patient with baseline obstructive sleep apnea is likely to have a Class IV Mallampati classification. The Mallampati classification is determined by having the awake patient in the sitting position open his or her mouth widely and then protrude the tongue completely forward. The clinician then documents which structures can be visualized.
   Class I: The soft palate, the fauces, the entire uvula, and the pillars are visualized.
   Class II: The soft palate, the fauces, and a portion of the uvula are visualized.
   Class III: The soft palate and the base of the uvula are visualized.
   Class IV: Only the hard palate is visualized.
5. *The thyromental distance.* This is often used as an indirect gauge of mandibular morphology. The ratio of a patient's overall height to his or her thyromental distance may be used as an indirect assessment of mandibular deficiency.

All patients with dentofacial deformities should have documentation by the anesthesiologist of the airway examination, as stated previously. The preoperative evaluation maybe conducted in a clinic setting or immediately before surgery. It is also recommended that the evaluation document the following:

- The status of the teeth (e.g., mobility, missing teeth, removable and fixed appliances, general oral heath);
- The neck circumference (this is an indirect indicator of obstructive sleep apnea)
- The overall body habitus
- Any presenting dentofacial deformity (e.g., maxillomandibular deficiency)
- Any anatomic cause of nasal airway obstruction (e.g., septal deviation, posterior choanal atresia, enlarged turbinates)

Prevention of Complications during Tracheal Intubation

According to the American Society of Anesthesiologists, four principles are central to the prevention of complications during tracheal intubation:

1. *The maintenance of oxygenation is essential.* Preoxygenation is performed before the induction of anesthesia. Mask ventilation is also used in between attempts at tracheal intubation.
2. *Trauma to the upper airway must be prevented.* The first attempt at tracheal intubation should be performed under optimal conditions (i.e., patient positioning, preoxygenation, and equipment preparation).
3. *The anesthesiologist should have a backup plan in place before initiation of the primary technique.* He or she must have the skills and equipment needed to execute the

backup plan for the patient with a difficult airway. The recent introduction of video-assisted laryngoscopy instruments have lessened the need for more invasive methods to secure the airway, such as the use of a fiber-optic bronchoscope and percutaneous techniques. The backup plan should include the eventuality that, if noninvasive techniques do not restore oxygenation, then cricothyroidotomy (which is generally the percutaneous airway method of choice) is ready to go. In an actual *"cannot intubate—cannot ventilate"* situation, immediate percutaneous access to the cricothyroid membrane is essential.

4. *The anesthesiologist should seek the best help available as soon as difficulty with tracheal intubation is experienced.* He or she should be aware of available backup personnel or colleagues who can be quickly called in to assist during an emergency.

Video 5

NOTE: In the patient with a dentofacial deformity, serious airway morbidity (e.g., cardiopulmonary arrest, or unnecessary tracheostomy)—although infrequent—is a much worse outcome than performing an awake fiber-optic intubation that may not have been necessary.

The presurgical airway evaluation by an experienced anesthesiologist provides a reasonable indication of potential intubation difficulty and should always be performed. The anesthesiologist must then make a judgment regarding whether anesthesia induction followed by direct laryngoscopy (as a first effort) followed by mask ventilation with percutaneous rescue (if direct laryngoscopy cannot be accomplished) is likely to be successful. The intrinsic limitations of the pre-anesthesia airway assessment mean that the preparation of an airway strategy for the management of unanticipated difficulties is the ultimate key to safe practice.

When the patient with a dentofacial deformity is felt to be at high risk for challenging airway management, advance planning ensures that necessary equipment and skilled personnel are available. The *"difficult airway"* is defined as the clinical situation in which a conventionally trained anesthesiologist experiences difficulty with face-mask ventilation of the upper airway, difficulty with tracheal intubation, or both. By definition, the difficult airway represents a combination of patient-specific factors, the specific clinical setting, and the skills of the individual practitioners.

Adequate *face-mask ventilation* may not be possible as a result of inadequate mask seal, excessive gas leak, or excessive resistance to the ingress or egress of gas. Difficulty with laryngoscopy is said to occur when it is not possible to visualize any portion of the vocal cords. *Difficult tracheal* intubation is defined as a tracheal intubation that has required multiple attempts in the presence or absence of true tracheal pathology. *Failed intubation* is defined as the inability to place an endotracheal tube after multiple intubation attempts.

The practical guidelines for the management of the difficult airway have been reported by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway.[6] The guidelines recommend the following: 1) a detailed evaluation of the airway; 2) a general physical examination; 3) additional patient-specific evaluations, as needed; 4) basic preparation for difficult airway management; 5) a strategy for the intubation of the difficult airway; 6) a strategy for the extubation of the difficult airway; and 7) arranging for follow-up care.

The anesthesiologist should have a preformulated strategy for the intubation of the patient with a dentofacial deformity and a difficult airway. This strategy should include the following:

1. An assessment of the likelihood and anticipated clinical impact of four basic problems that may occur alone or in combination:
   - Difficult ventilation
   - Difficult intubation
   - Difficulty with patient cooperation
   - Difficult tracheostomy (cricothyroidotomy)
2. A consideration of the relative clinical merits and feasibility of the three basic airway management choices:
   - Awake fiber-optic intubation versus intubation after the induction of general anesthesia
   - The use of noninvasive techniques for the initial approach to intubation (e.g., direct conventional laryngoscopy, laryngeal mask airway–assisted airway attainment, video-assisted laryngoscopy) versus the use of invasive techniques (e.g., percutaneous cricothyroidotomy, tracheostomy)
   - The preservation of spontaneous ventilation during intubation attempts versus the ablation of spontaneous ventilation during intubation attempts
3. The anesthesiologist must select a primary approach to the difficult airway:
   - Awake fiber-optic intubation in the patient who cannot be adequately ventilated and who will be difficult to intubate
   - The patient who can be adequately ventilated but who will be difficult to intubate
   - The life-threatening situation in which the patient cannot be ventilated or intubated and who will require immediate cricothyroidotomy or tracheostomy
4. The anesthesiologist should formulate in advance an alternative plan in the event that the primary approach is ineffective.

Special Airway Considerations in the Patient with a Dentofacial Deformity

The patient with a dentofacial deformity who is scheduled to undergo orthognathic surgery requires nasotracheal intubation as a first choice. The consideration of patient-specific intubation difficulties should be discussed between the surgeon and the anesthesiologist before arrival in the operating room (see Figure 11-1).

Difficulty with passing the endotracheal tube through the external nasal valve and the nasal cavity:

- The dentofacial deformity patient will often have an obstructed nasal airway as a result of a combination of scarred external nasal valves; a deviated septum; hypertrophic turbinates; a constricted bony nasal cavity (e.g., floor of the nose, lateral nasal walls); or posterior choanal atresia.

Difficulty with passing the endotracheal tube past the soft palate and nasopharyngeal walls into the oropharynx:

- In the patient with a cleft palate, a pharyngoplasty may be in place. This will result in limited lateral ports if a superiorly based pharyngeal flap is in place. There may be a limited central port if an orticochea (sphincteroplasty) flap is in place. Either of these forms of pharyngoplasty in the patient with a cleft palate may interfere with the passage of a nasotracheal tube.
- If the endotracheal tube cannot be passed through the nose and into the oropharynx, then the insertion of the endotracheal tube through a submental (skin) incision maybe carried out. This will accomplish intubation objectives but avoid interference with the occlusion during surgery. To accomplish the submental approach, the endotracheal tube is first passed through the oral cavity and into the pharynx. With the use of a laryngoscope, it is then passed through the vocal cords. The patient will be adequately ventilated while the submental approach is accomplished. A sharp submental incision is made, and this is followed by blunt dissection just behind the mandible and then into the mouth. The end of the endotracheal tube is pulled through the floor of the mouth and out of the submental incision for the administration of anesthesia.

Difficulty with inserting and using the laryngoscope to visualize the vocal cords as a result of limited mouth opening:

- The presenting dentofacial malformation may result in limited mouth opening (e.g., Treacher Collins syndrome, hemifacial microsomia)
- Temporomandibular joint pathology (bony or fibrous ankylosis) will limit the extent of mouth opening (i.e., the interincisal distance).
- Masticatory muscle spasm will limit mouth opening and may be confused with bony or fibrous temporomandibular joint ankylosis.

Difficulty with visualizing the vocal cords as a result of mandibular hypoplasia with a retro and superior positioned tongue within a limited floor of the mouth space:

- The presenting mandibular malformation or deformity (e.g., moderate to severe hypoplasia) will result in the retro and superior positioning of all of the soft tissues of the floor of the mouth and the anterior neck. This will result in limited visualization of the vocal cords. This may be true even for a non-obese patient in the neck-extended position during a full jaw-thrust maneuver.

Difficulty with visualizing the vocal cords as a result of limitations in the range of motion of the neck:

- A percentage of patients with dentofacial deformities will have congenital limitations in the range of motion of the neck (e.g., hemifacial microsomia [Goldenhar variant], Klippel–Feil anomaly). This should be assessed before the patient arrives in the operating room.
- For the patient with baseline cervical spine anomalies, evaluation by a spine surgeon and specialized radiograph studies may be indicated in the outpatient setting before arrival in the operating room.
- Possible advantages of intraoperative spinal monitoring should be discussed before arrival in the operating room.

It is likely that the orthognathic surgeon will be most familiar with the nasal, oral, pharyngeal, temporomandibular joint, and cervical spine patient-specific anatomy. Potential locations of obstruction and limitations in neck and jaw range of motion should be discussed before arrival in the operating room. The surgeon should be ready to assist with the passage of the nasotracheal tube through the external nasal valve and the nasal cavity and into the oropharynx. The anesthesiologist will then complete direct laryngoscopy, video-assisted laryngoscopy (i.e., GlideScope), or fiber-optic intubation to pass the endotracheal tube through the vocal cords.[144,146] In anticipation of the possible need for percutaneous airway management, the team should have the skill and readiness of equipment to complete either a cricothyroidotomy or a formal tracheostomy, as indicated.

Immediate Preintubation Preparation of the Airway

Preparation of the nasopharynx is useful before attempting nasotracheal intubation. It begins with questioning the awake patient about the ease of breathing through one nares versus the other. Preparation of the nasal airway with topical agents just before entering the operating theater is also routine; this allows the agents to reach peak effect before intubation. Topical vasoconstrictors such as oxymetazoline (a direct-acting sympathomimetic vasoconstrictor) or Neo-Synephrine (an alpha-adrenergic agonist and a potent vasoconstrictor) will reduce nasal mucosal edema, thereby improving the patency of the nares and also reducing the potential for bleeding.

After the nasal airway is decongested and sufficiently anesthetized, sequential dilation with a nasopharyngeal

airway tube (nasal trumpet) is recommended to clarify the expected ease or difficulty of passage of the nasotracheal tube. The nasopharyngeal airways should be lubricated with either standard surgical lubricant or topical lidocaine jelly, which may also be mixed with topical vasoconstrictor. The use of benzocaine spray as a topical anesthetic is another option; however, as a result of the rapid uptake of this drug, the high rate of absorption through the mucus membranes, and the risk of toxicity judicious use is warranted. Methemoglobinemia has been reported to occur with benzocaine spray and other local anesthetics. This may occur when the ferrous ion (Fe^{+2}) of the hemoglobin molecule is converted into the ferric ion (Fe^{+3}), thereby resulting in decreased oxygen-carrying capacity. If this occurs, treatment includes supplemental oxygen and intravenous methylene blue.

Glycopyrrolate (Robinul) is a synthetic quaternary amine with muscarinic anticholinergic and antisialagogue properties. The expected sympathetic reflex that occurs during the induction of general anesthesia may result in copious secretions in the oropharynx, thereby obscuring laryngoscopy and making a successful intubation difficult. Secretions can be managed with an antisialagogue (e.g., glycopyrrolate), which will also improve the oropharyngeal surgical field. However, glycopyrrolate will tend to increase heart rate and blood pressure as a result of its anticholinergic effects. This may need to be attenuated with appropriate beta-blocker or vasodilator therapy.

A commonly used protocol for the preintubation preparation of the nasopharyngeal airway includes the following:

- Pretreatment with the judicious use of a topical vasoconstrictor (e.g., oxymetazoline, Neo-Synephrine) to shrink the nasal mucosa
- Pretreatment with a topical anesthetic, including topical lidocaine jelly
- Sequential dilation with lubricated nasopharyngeal airways (i.e., the nasal trumpets) to ease the passage of the nasotracheal tube

Strategy for Extubation after Orthognathic Surgery

After orthognathic surgery, all patients should be considered to have a difficult airway at the time of extubation. An extubation strategy is a logical extension of the planned intubation strategy for the patient with a difficult airway. The extubation strategy should be specific to the patient, and it should take into account preoperative anatomic factors; preexisting medical conditions; intraoperative findings; patient-specific swelling and intra-oral bleeding; and the patient's response to the anesthesia techniques that were used.[37,43,62,124,257,278]

Factors to consider include the following:

- Baseline preoperative obstructive sleep apnea
- Baseline limited neck range of motion
- Excessive sedation with the inadequate return of reflexes
- Continued intranasal or intraoral hemorrhage with pooling in the pharynx, which may go unrecognized and cannot be easily suctioned
- Excessive swelling within the intranasal, intraoral, and pharyngeal components of the upper airway
- Laryngeal swelling or spasm
- The potential for immediate postextubation vomiting
- The patient-specific presence of in-place intermaxillary wires, elastics, or intra-oral splints

The formulated extubation strategy should include the following:

- Strong consideration of the advantages of awake extubation versus extubation before the return of consciousness
- The formulation of an airway management plan to be implemented if the patient is not able to maintain adequate ventilation after extubation
- An evaluation of the general and patient specific clinical factors that may result in difficulty with mask ventilation after extubation
- Consideration for the short-term maintenance of a device that can serve as a guide for expedited reintubation. A semi-rigid airway device called a *tube exchanger* can be inserted through the lumen of the nasotracheal tube and into the trachea before the nasotracheal tube is removed. This device can then be used to facilitate the reinsertion of the nasotracheal tube should reintubation be required. It also allows for the limited ability to both oxygenate and ventilate the patient during the performance of reintubation maneuvers.
- A plan for percutaneous intubation (i.e., cricothyroidotomy or tracheostomy) with available equipment at the location of patient extubation (i.e., operating room, recovery room, or intensive care unit) with the skilled personnel required to complete the procedure, if required
- Discussion between surgeon and the anesthesiologist regarding patient-specific limitations in mouth opening (e.g., intermaxillary wires, elastics, masticatory muscle spasms, intra-oral splints)

Extubation Criteria for the Orthognathic Patient

With the administration of neuromuscular blocking agents as well as multiple combinations of various classes of drugs including opioids, barbiturates, and benzodiazepines, the modern hypothesis of general anesthesia has evolved to be understood as a process that requires a state of unconsciousness of the brain as well as a blockade of noxious stimuli, both centrally and peripherally. Recognition of the stage or plane of anesthesia by the clinician is important at all times

but especially at the end of the operation, when the patient must be recovered in a safe, efficient manner.

There are four classically described stages of anesthesia that are based on physical signs (e.g., respiratory status, hemodynamic status, ocular signs, muscle tone) that demonstrate the depth of anesthesia.

- Stage I is present when there is analgesia and amnesia but no loss of consciousness.
- Stage II is the period after a loss of consciousness at which point the patient's reflexes are still present, the breathing pattern is irregular, and there may be excitability. The pupils will be dilated, and there will be a disconjugate gaze.
- Stage III is considered surgical anesthesia, when there will be lack of response to surgical stimulation. Loss of the eyelash reflex is a reliable indicator of this stage. Within Stage III, there are additional planes or levels of consciousness that correspond with the amount of anesthetic delivered. The plane of anesthesia that is desired depends on the surgery being performed.
- Stage IV describes cardiovascular and respiratory failure as a result of the overadministration of anesthetic, which results in brain stem and medullary depression. This is potentially fatal.

When the need for surgical anesthesia is over, the inhalational and intravenous agents are stopped, and the patient will emerge from Stage III anesthesia (i.e., the surgical plane of anesthesia). It is important to support the patient through Stage II and into Stage I, which is when he or she can generally be safely extubated.

Potential pitfalls of the premature extubation of any patient include laryngospasm, excessive secretions or bleeding leading to airway compromise or aspiration, and inadequate airway drive as a result of residual anesthetic agents or narcotics, with the resultant need for reintubation. *Patients who are undergoing orthognathic surgery have additional and unique immediate postextubation airway concerns.* **Consequently, these patients need to meet more stringent criteria for extubation than would be anticipated for a non-intranasal or non-intraoral procedure.** Mouth opening will be limited as a result of the presence of surgical trauma and swelling of the muscles of mastication. Guiding elastics to secure the jaws together and an intra-oral (occlusal) splint are likely to be in place. Concerns about osteotomy stability may limit the forces that can be safely applied on the jaws should either mask ventilation or reintubation be required. Partial obstruction of the nasopharynx as a result of varied degrees of mucous, fresh blood, and clotting is to be expected. For all of these reasons, in the event of an airway emergency after extubation, the orthognathic patient will be difficult to mask ventilate, and there will be only limited time to consider an alternative approach to resecure the airway. The option of blind nasotracheal intubation will be even more difficult than it would have been before surgery. Orotracheal intubation will require the removal of elastics and be difficult at best. The inability to adequately mask or reintubate the patient either orally or nasally will necessitate an emergency cricothyroidotomy or tracheotomy.

Negative pressure pulmonary edema is an uncommon complication that occurs during the extubation of the trachea in approximately 0.1% of cases.[29] It is believed to be a result of laryngospasm. Upper airway obstruction from glottis closure leads to marked inspiratory efforts, which generates negative intrathoracic pressure. This may cause negative-pressure pulmonary edema and, rarely, hemoptysis. Immediately after extubation, the patient will be noted to have marked respiratory distress followed by edema fluid and decreased arterial oxygen saturation, with rising partial pressure of CO_2 levels. A chest radiograph will likely show bilateral pulmonary infiltrates. The most effective form of management is reintubation followed by positive end-expiratory pressure for 12 to 24 hours.

Before the Extubation of the Orthognathic Patient

- Any deliberate hypotensive techniques should be ceased with a return to preoperative hemodynamic stability.
- Any hypothermia should be addressed with rewarming techniques, including temperature-controlled intravenous fluids and warming blankets.
- The patient's breathing pattern should be regular, with adequate tidal volume (i.e., 6 to 10 mL/kg) and rate of respiration (i.e., 10 to 20 breaths/min).

If the patient was chemically paralyzed, this must be reversed with appropriate agents, (e.g. neostigmine and an anticholinergic agent such as glycopyrrolate). Reversal should be monitored with a twitch monitor, which consists of two electrodes placed at a motor nerve. The ulnar nerve is commonly stimulated to observe the contraction of the adductor pollicis muscle. The return of train-of-four twitches with a ratio of more than 0.9 and with sustained tetany is a method that is used to provide information about the depth of neuromuscular blockade throughout the case and through its reversal at the end. It also allows for the differentiation of depolarizing and nondepolarizing neuromuscular blockade.

- If bispectral index monitoring is used to assess the depth of anesthesia, a return to preoperative levels should be documented.
- Adequate analgesia is maintained with appropriate opioids, but titration with maintenance to a physiologic respiratory rate and tidal volume is required.
- The patient should be sufficiently awake and should have spontaneous eye opening with a conjugate gaze.
- The patient should be able to follow commands (e.g., sustained head lift and hand grip).
- A nasopharyngeal airway (i.e., a nasal trumpet) may be placed to assist with ventilation after extubation.

Checklist of Benchmark Airway Parameters Before Extubation

1. Spontaneously ventilating
2. Paralysis reversed adequately (i.e., sustained tetany without fade for >5 sec)
3. Vital signs stable
4. No longer in Stage II anesthesia
5. Negative inspiratory force of <–20 mm Hg (i.e., you can take off the bag, cover the hole with your hand, and have the patient suck in while you are watching the pressure gauge)
6. "Leak test" for the evaluation of pharyngeal and laryngeal edema
7. Benchmark respiratory parameters:
   - Tidal volume >6 cc/kg
   - Vital capacity >15 cc/kg
   - Blood oxygen saturation >90%
   - Respiratory rate <25 breaths/min
   - $paCO_2$ <45 mmHg

In-Hospital Convalescence After Orthognathic Surgery

After extubation, initial management takes place in a recovery room setting. Transfer to a monitored bed either in an intensive care unit or a step-down or telemetry unit is generally preferred. Continuous awareness of the potential for impending respiratory compromise and the need for monitoring to confirm hemodynamic stability is essential early after extubation.[263]

Airway Needs

Respiratory issues are of immediate postoperative concern in the orthognathic surgery patient.* The individual must be able to maintain his or her airway as documented by the ability to adequately oxygenate and ventilate. Multiple factors may compromise the airway, including limitations in *nasal breathing* as a result of the following: 1) the Le Fort I down-fracture with tears in the nasal mucosa; 2) specific intranasal procedures that were carried out (i.e., septoplasty, inferior turbinate reduction); and 3) edema after nasotracheal tube removal. The *oral airway* will be partially obstructed by the following: 1) ongoing bleeding, secretions, and swelling; 2) the use of guiding elastics; and 3) the presence of an acrylic intra-oral occlusal splint secured to the maxillary dentition. A nasopharyngeal trumpet may be helpful to improve the nasal airway early after extubation. The guiding elastics should be removed, if needed, to improve the oral airway. Active and frequent bedside suctioning is carried out. Supplemental oxygen given via a face tent provides an additional reserve through the nose and mouth; it is titrated to maintain pulse oximetry (i.e., oxygen saturation) of more than 95%, as described later in this chapter.

*References 17, 30, 47, 52, 72, 109, 112, 137, 141, 148, 153, 176, 183, 192, 194, 199, 246, 268, 271, 275.

Monitoring Equipment

Continuous pulse oximetry is essential. This allows for the beat-to-beat monitoring of hemoglobin saturation. It uses a pair of light-emitting diodes to measure the amount of hemoglobin in the oxyhemoglobin formation as a percentage. Normal oxygen saturation ranges from 97% to 100%. It is important to remember that pulse oximetry is not a measure of ventilation but rather of oxygenation. Factors that can result in errors of the "pulse ox" reading include hypoperfusion of the extremity being used for monitoring, high central venous pressures, and carboxyhemoglobin with carbon monoxide poisoning or methemoglobinemia. For these reasons, pulse oximetry does not replace arterial blood gas sampling for a precise measurement of arterial oxygenation. Neither technique is a substitute for a direct physical examination. Recently, technology advances have allowed for the monitoring of both pulse oximetry and capnography in one device. This is done with the use of microstream capnography via bedside nasal prongs along with pulse oximetry. These modalities together improve the ability to assess the adequacy of ventilation and oxygenation during the perioperative period.

Five-lead electrocardiography allows for the monitoring of the cardiac waveform. The most commonly used leads are II and V5 for diagnosing cardiac arrhythmias and cardiac ischemia.

Noninvasive blood pressure monitoring should be used even when an arterial line is also present postoperatively. The continuous invasive arterial blood pressure monitor may be maintained for 12 to 24 hours postoperatively. This will assist with the monitoring of the patient's arterial blood pressure in a beat-to-beat manner. It may allow for the improved accuracy of diagnosis and better direct the treatment of hypovolemia and hypotension. The arterial line can also be used to draw blood for postoperative laboratory values instead of subjecting the patient to a fresh needlestick.

Whenever there is use of DHA as well as a risk of postoperative bleeding, the maintenance of the intraoperatively placed *Foley catheter* to monitor urine output soon after surgery is useful. A catheter may be helpful to assess the success of fluid resuscitation and for patient comfort. As a baseline, normal hourly urine output for an adult is 0.5 mL/kg/hr; for a child, it is 1 mL/kg/hr.

Measuring the patient's *temperature* both intraoperatively and postoperatively is important. Temperature elevation is a late sign of malignant hyperthermia, which is very rare (i.e., 1 in 50,000 for adults). More commonly, through temperature monitoring, the patient is found to be hypothermic secondary to peripheral vasodilation caused by inhaled anesthetic gases and exposed extremities. Hypothermia can cause the patient to become coagulopathic and to

develop arrhythmias and disorders of the metabolism. Core body temperature can be measured via a temperature-sensing Foley catheter. For this modality, the Foley catheter houses a thermistor at the tip that allows for continuous core-temperature monitoring in a safe and minimally invasive manner.

Sequential compression devices placed on the lower extremities are used intraoperatively and maintained during the postoperative period to limit the formation of deep venous thrombosis. These devices increase the velocity of venous blood return to the heart, thereby decreasing venous stasis. In addition, the mechanical compression results in increased fibrinolytic activity within the vascular system. Stockings should be maintained while the patient is immobilized. On postoperative day 1, the patient should be ambulated with assistance, at which point the compression stockings may be discontinued. Multiple studies have documented that early ambulation improves recovery and results in a decreased risk of deep venous thrombosis, the return of bowel function, and earlier hospital discharge.[6]

Wound Care

Intraoral hygiene with Peridex (chlorhexidine 0.12%) and toothbrushing are performed three to five times daily. This is to decrease the bacterial load and the levels of biofilm in the oral cavity. This is especially important, because there are orthodontic brackets, elastics, splints, and exposed sutures in place near and at the incisions. An active oral hygiene routine is initiated the night after surgery by a health care professional. The patient and his or her family are specifically instructed in the techniques by the day after surgery.

In general, there are no external bandages after orthognathic surgery. The patient is encouraged to shower and shampoo his or her hair and to wash his or her face the day after surgery and at least daily thereafter.

Diet

Initial hydration, electrolyte balance, and nutrition are maintained though intravenous fluids. The night of surgery, oral intake is initiated. The orthognathic patient must tolerate liquids for adequate nutrition and hydration before discharge. Inadequate liquid intake may occasionally result in dehydration and the need for readmission after discharge. Caloric requirements in the healthy, non-hospitalized, and non-stressed individual is 15 to 20 Kcal/kg/day. The caloric need will increase substantially in the postsurgical patient, who is, by definition, under stress. A general guideline of caloric need in the patient after orthognathic surgery is 25 Kcal/kg/day. In addition, protein requirements can be doubled from 1 gm/kg of ideal body weight per day to 2 gm/kg of ideal body weight per day.

Surgical trauma to the lips and cheeks initially results in the diminished ability to achieve full lip seal. Without sufficient lip seal, the ease with which one can swallow liquids or drink from a cup is limited (see Chapter 8). A feeding syringe with a soft wide bore tip is initially used. It is placed in the vestibule between the cheek and the posterior teeth to facilitate the direction and depth of entry of liquids. The fluid bolus is injected, and the patient then seals the lips and swallows. The clear liquid diet is rapidly advanced to full liquids to achieve the needed caloric and nutritional intake. The patient transitions from syringe feeding to the use of a "sippy cup" or a squeezable water bottle and then to drinking from a soft glass as soon as he or she is able.

Nausea and Vomiting Management

Postoperative nausea and vomiting are common anesthetic concerns for the patient. If these conditions are not managed, they may in rare cases result in aspiration.[236,256] Steps taken to decrease their likelihood include gastric suctioning at the end of the procedure before extubation and the use of prophylactic medications. All orthognathic patients are given prophylactic antiemetic therapy. A medication regimen may include the following: glucocorticoids such as dexamethasone at the onset of surgery; ondansetron (Zofran) or granisetron (Kytril) 15 minutes before the conclusion of surgery; metoclopramide (Reglan); and the judicious intake of liquids immediately after extubation. Multimodal antiemetic therapy in the recovery room should be employed for refractory cases of nausea and vomiting; this may include promethazine, compazine, and repeat doses of ondansetron-like agents. Appropriate postoperative patient monitoring and bedside access to a mouth-suctioning device are essential. As long as the patient can maintain protective airway reflexes, episodes of vomiting (with only liquids on the stomach) should have minimal serious sequelae.

Intravenous Fluid Therapy

The preoperative number of hours of "nothing-by-mouth" status, the individual's body weight, and the intraoperative fluids given and lost need to be quantified. This process allows for a precise representation of the patient's fluid balance and ongoing fluid and electrolyte needs. The intravenous fluid needs must account for both sensible and insensible losses. Once maintenance fluids are calculated, a determination of estimated fluid deficit (EFD) should be made. Intraoperative third space loss and blood loss will also be taken into account. Fluid administration needs to be titrated to maintain hydration and desired urine output.

A starting point to estimate maintenance fluid needs after surgery can be given with the use of the following formula:

- 4 mL/kg/hr for the first 10 kg of body weight
- 2 mL/kg/hr for the next 10 kg of body weight
- 1 mL/kg/hr for every 1 kg of body weight above 20 kg

Pain Management

The postoperative orthognathic patient has pain requirements that are similar to those of any other surgical patient. Analgesia is required for the progression of the patient to recovery. Initial postoperative requirements are best maintained with intravenous medication, whether it is administered by the nursing staff or patient controlled. Multiple studies have confirmed that patient-controlled analgesia is safe, effective, and not likely to result in oversedation or respiratory compromise. Intravenous morphine sulfate is routinely used. By the morning after surgery, the patient is transitioned to a liquid form of opioid that taken at 4- to 6-hour intervals as needed for analgesia. It would be unusual for the patient to require or request opioid pain control by the second week after surgery. The transition from intravenous analgesics to an oral form is essential for the patient's discharge and his or her comfortable transition to home care.

Antibiotics

Multiple studies have confirmed the benefit of prophylactic doses of antibiotics for clean-contaminated (Class II) surgery and specifically for orthognathic surgery to decrease wound infection rates. This is typically initiated as a prophylactic dose of the first-generation cephalosporin cefazolin (Ancef); 15 to 20 mg/kg and up to 1 g is given before surgical incision and then every 6 hours. The postoperative course of intravenous antibiotics continues while the patient is still in the hospital. Antibiotics are then given orally upon discharge for a total of no more than a 5-day course. Opinions vary with regard to the extent of use of antibiotics for orthognathic surgery. Bentley and colleagues performed a randomized controlled trial that compared a 1-day regimen with a 5-day regimen of antibiotics for patients who were undergoing orthognathic surgery.[24] A group of 30 patients who were undergoing combined maxillary and mandibular osteotomies was divided equally. Nine out of 15 patients in the 1-day antibiotic group developed postoperative infection, whereas only 1 out of 15 patients in the 5-day antibiotic group did. The authors concluded that a 5-day course of antibiotics is useful to decrease the risk of postoperative infection (see Chapter 16).

Nasal Medications

The use of specific nasal medications after surgery varies by surgeon preference. Many surgeons recommend that, after surgery, several days of an intranasal decongestant be given to open the nasal airway and improve patient comfort. These can include Neo-Synephrine nasal spray, oxymetazoline (Afrin) nasal spray, or a corticosteroid such as Rhinocort. In addition, saline nasal spray improves the humidification of the nasal passages and limits the drying of the nasal mucosa, which may decrease the risk of epistaxis and improve patient comfort. A pure nasal saline spray has the advantage of not having a rebound effect as compared with the pharmacologic agents. This is the requirement that I prefer.

Criteria for Discharge from Hospital

Discharge planning for the orthognathic patient should begin before surgery. There should be ample preoperative communication with the patient and the patient's family or significant others to prepare for the anticipated postoperative care requirements, including medications, diet, oral and body hygiene needs, and activity level. Basic criteria for discharge from the hospital include the following:

- The ability to ingest sufficient liquids orally (i.e., hydration and nutrition)
- The absence of significant fever
- Stable vital signs, including the maintenance of pulse-oximetry documented oxygenation while sleeping
- The absence of continued nausea and vomiting
- Sufficient ambulation to carry out necessary activities of daily living in conjunction with a designated family member, friend, or caregiver
- Adequate pain control with oral analgesia while in the hospital
- The demonstrated ability to achieve required body and oral hygiene

At-Home Convalescence and Outpatient Care After Orthognathic Surgery

When feasible, our preferred outpatient regimen involves weekly office visits for 5 weeks after orthognathic surgery. Although the frequency and duration of routine postoperative office visits will vary from surgeon to surgeon, there is no substitute for a face-to-face discussion and a hands-on examination with the patient to clarify expected progress, to identify potential problems, and to institute timely treatment during the early phases of healing.

Important aspects to monitor early after orthognathic surgery include the following: 1) diet, hydration, and nutrition; 2) oral and body hygiene; 3) physical activity level; 4) emotional well-being; 5) medication use; 6) swelling and wound healing; 7) occlusion and jaw mobility; and 8) adequacy of the oral and nasal airways. The need for physical therapy related to A) lip seal and control exercises, B) sensory retraining exercises, and C) mouth-opening exercises is also assessed. Each of these parameters is addressed during each postoperative office visit. When weekly visits with the surgeon are not geographically convenient, an appropriate clinician closer to home (i.e., an orthodontist and surgeon) can generally be found. This is best supplemented with a phone call and the viewing of e-mailed facial photos sent to the primary surgeon.

Patient Education Materials

Patient Instructions for Orthognathic Surgery

The purpose of these basic instructions is to help you prepare and then recover from your operation with as little discomfort and inconvenience as possible.

Preoperative Instructions

1. During the 2 to 6 weeks before your planned operation, you will return to my office to have current dental and facial records taken; to undergo further head and neck examination; and to allow for the completion of analytic model planning.
2. During the 2 to 6 weeks before your surgery, make arrangements for a physical examination by your family physician that includes necessary laboratory tests to confirm your health. We will provide you with a form for your general physician to complete.
3. Do not take any aspirin, aspirin-like products, or any other medications that may increase bleeding for at least 3 weeks before surgery. Aspirin and aspirin-like products tend to increase bleeding during surgery and bruising postoperatively.
4. If you take or have taken a bisphosphonate medication (e.g., for osteoporosis or osteopenia therapy), you must let us know, because your risk for bone-healing difficulties may be increased.
5. Be sure that you do not smoke and that there are no nicotine products in your bloodstream for at least 3 weeks before and 2 weeks after surgery. Nicotine in the bloodstream jeopardizes wound healing. Smoke that is chronically ingested by the lungs may result in pulmonary complications that will hinder optimal healing.
6. Starting 2 days before surgery, we request that you shampoo your hair and shower at least once per day. The morning of surgery, you may also shower and shampoo your hair again.
7. Do not eat or drink anything after midnight the night before surgery, not even a sip of water. You may brush your teeth, but do not swallow the water.

Postoperative Instructions

1. In general, you will remain in the hospital for 1 or 2 nights during your initial recovery. When you are up and around, drinking enough fluids, and have recovered some of your strength, you will be able to return home to the care of your family.
2. Instructions for a high-protein blenderized (pureed) diet will be discussed with you. In general, the pureed (blenderized) diet will continue for 5 weeks, after which you will gradually return to the eating of regular foods.
3. Exercising your lips (e.g., squeezing them together for closure) during the first several days after surgery is helpful. By doing so, you will more rapidly regain lip control, reduce facial swelling, and find it easier to swallow fluids and control your saliva.
4. You will begin brushing your teeth with a soft toothbrush the day of the operation. We will prescribe a special antimicrobial mouth rinse to reduce the plaque (bacteria) buildup on your teeth.
5. In general, no facial bandages will be used after surgery. You should take a shower and wash your hair and face the day after surgery. Initially, you should have someone close by when you shower, because you may feel unsteady on your feet.
6. It is advisable to sleep with your head in an elevated position (e.g., on two pillows) for at least the first week after surgery. This helps with the natural drainage of fluids in the facial area, and it also helps to decrease swelling.
7. Nasal congestion (i.e., difficulty breathing through the nose) is to be expected immediately after surgery. The congestion generally takes 5 to 7 days to significantly clear. Until then, frequent steamy showers and the use of saline nasal sprays will be helpful. You should avoid blowing your nose after surgery, because doing so may increase the risk of bleeding. When you sneeze, let the air go through your mouth to limit the pressure in your nose.

8. When you get home, you should take the prescribed pain medication as needed. Tylenol may be substituted when your pain has diminished. Avoid taking aspirin or aspirin-like products for an additional 2 weeks after surgery.
9. Your sleep schedule will be irregular during the initial weeks after surgery. You may substitute Benadryl for the pain medication to assist with sleeping, but only after permission is received from your surgeon.
10. You will be given a prescription for an antibiotic. Take it as directed until the supply is exhausted. If you develop a skin rash, diarrhea, or a vaginal infection, stop the medication and contact your surgeon, because these problems may be related to your prescription.
11. Do not drink any beverages that contain alcohol, take any non-prescribed medications, or drive a motorized vehicle until you have been given permission to do so.

Additional Considerations

1. A cold pack placed over the cheek and neck region on each side of the face is useful during the initial 24 to 36 hours after surgery to limit swelling. Nevertheless, you will be swollen, and your skin will be discolored (i.e., black, blue, green, and yellow) for several weeks after surgery. The swelling and discoloration are never the same on the two sides of the face and neck, and they will be seen halfway down your chest. Remember that each side of the face heals somewhat independently. The initial soft-tissue swelling will not influence the final results. Although the swelling decreases significantly by 5 weeks after surgery, 6 to 12 months is required for all swelling to subside.
2. There will be numbness or decreased sensation in specific regions of your mouth and face. This takes some time to get used to, and it will improve considerably. The location of the diminished sensibility of the skin of the face and the mucous membranes of the mouth will be dependent on the specific procedures that are carried out. I will explain this to you in detail at your first consultation and again during office visits before your operation; this information will also be found on your informed consent document.
3. In general, at 5 weeks after surgery, basic healing is sufficient enough for you to gradually return to physical activities such as jogging, bicycling, and aerobics. At this stage, progression to a more regular (chewing) diet is also encouraged.

Physical Therapy after Orthognathic Surgery

1. Early after orthognathic surgery the loss of full lip control/seal results in drooling and difficulty swallowing a bolus of liquid. The lip-control difficulty results from a combination of factors, including A) surgical trauma to the soft tissues of the lips; B) the expected diminished sensation; C) the change in the position of the jaws and teeth; and D) the presence of an intra-oral occlusal splint, elastics and orthodontic lugs. Instituting active lip closure and control exercises beginning the day after surgery will help you to regain lip-seal control for ease of swallowing and managing your saliva.
2. Within the first few weeks after surgery, instructions will be given to help you to achieve the gradual return of normal mouth opening. If the adequate return of mouth opening, speech articulation, and lip control are slow in coming, then the institution of active range-of-motion mouth exercises and speech therapy will be arranged.
3. Some individuals have more difficulty than others adjusting to the expected loss of sensation after a Le Fort I maxillary osteotomy (involving the infra-orbital nerves) or sagittal split ramus osteotomies of the mandible (involving the inferior alveolar nerves). The institution of sensory retraining exercises may be helpful to desensitize you to the altered sensibility and the expected gradual recovery in specific facial and oral locations.

Jeffrey C. Posnick, DMD, MD
Director, Posnick Center for Facial Plastic Surgery

Physical Therapy after Orthognathic Surgery

- Lip Closure/Control Exercises
- Mouth-Opening Exercises
- Sensory Retraining Exercises

LIP CLOSURE/CONTROL EXERCISES

Patient Instructions (to begin the day after surgery)

Keep in mind that many patients with jaw deformities (e.g., long face growth pattern) have never been able to easily obtain full lip seal. Beginning the day of surgery, we encourage active lip closure/control exercises. Initially, the exercises are carried out by the patient under the direction of a health care professional. The patient should look at his or her lips with the use of a handheld mirror. Attempting to squeeze the lips together while viewing them in a mirror generally provides for a successful lip seal within 12 to 24 hours. Until lip seal can be achieved, it is difficult to effectively swallow liquids without drooling a portion of the liquid out of the mouth. After a consistent lip seal is achieved, the ability to swallow saliva and to drink sufficient quantities of liquids for the maintenance of hydration and adequate caloric intake is the norm. With diligent effort, the required level of lip control is generally achievable by 24 to 48 hours after surgery.

MOUTH-OPENING EXERCISES (MODIFIED UNIVERSITY OF NORTH CAROLINA INSTRUCTIONS)

Level I Patient Instructions (2 to 5 weeks after surgery)

Basic Mouth-Opening Exercises

Do these mouth-opening exercises at least three times a day for 2 to 3 minutes each time: once in the morning, once at midday, and again in the evening.

1. First, remove the elastics, and then practice opening your mouth and moving your jaw side to side by just using your jaw muscles.
2. Do not try to open or move beyond what causes only mild discomfort for a short period of time. Do not force the opening if it hurts.
3. Do not do the mouth-opening exercises with your elastics on. Avoid forcefully opening your mouth by straining against the rubber bands that hold your jaws together.

By the end of the third week, you may be able to open your mouth wide enough to get one finger between your front teeth when the elastics are off. By the end of the fifth week, you may be able to get two fingers between your teeth when your elastics are off.

Hold-and-Relax Exercises

If you cannot open your mouth wide enough to get one finger between your front teeth at the end of the third week, start these hold-and-relax exercises.

1. Open your mouth about half of the amount that is comfortable.
2. Fold your hand into a fist, and place your fist under your lower jaw.
3. Using gentle pressure, push up with your fist as if you are trying to close your mouth.
4. Use your jaw muscles to try and open your mouth against the pressure of your fist. Hold this pressure for about 5 seconds, and then remove your fist and close your mouth.
5. Next, spend 30 to 60 seconds moving your jaw side to side and gently stretching and opening your mouth just using your jaw muscles.
6. Repeat the hold-and-relax exercise followed by moving the jaw side to side about five times.

Level II Patient Instructions (5 to 9 weeks after surgery)

Hold-and-Relax Exercise

Do two or three repetitions of the hold-and-relax exercise three times a day: in the morning, at midday, and in the evening. (See the Level I instructions for this exercise.)

Finger-Stretch Exercise

1. Place your middle finger on your lower teeth in the bicuspid region, and place your thumb on your upper teeth in the bicuspid region.
2. Apply pressure with your fingers so that it creates the feeling that you are stretching the jaw muscles. There will be some feeling of tightness or mild discomfort. Hold this for 5 seconds, and then release your fingers and close your mouth.

3. Next, move your jaw side to side and open and close your mouth using your jaw muscles for 30 to 60 seconds.
4. Repeat the finger-stretch exercise but with your fingers on just one side of your mouth at a time. Follow this with the side-to-side exercise.

Do the finger-stretch exercise three times on each side. Each time, try to slightly increase the finger pressure to produce more opening. Producing a feeling of mild discomfort is okay, but do not push enough to create pain.

SENSORY RETRAINING EXERCISES (MODIFIED UNIVERSITY OF NORTH CAROLINA INSTRUCTIONS)

Level I Patient Instructions (2 to 5 weeks after surgery)

Basic Touch Exercises

Do the touch exercises with a brush (i.e., a toothbrush, hairbrush, or makeup brush) at least three times a day for 2 to 3 minutes each time: in the morning, at midday, and in the evening.

1. Start by looking in the mirror, and watch what you are doing with the brush.
2. First, alternate touching and stroking your face with the brush.
3. When you start the exercise, make long strokes that extend from one side of the face to the other.
4. As you do the exercises, vary where you first touch your face before starting the stroke. Do this on different parts of your face (i.e., forehead, cheeks, chin, and upper and lower lip).
5. The brush should be moved at the same rate that you might use your fingertips to touch or examine a piece of cloth.
6. Be sure to move the brush around on both sides of your face. Do not spend all of your time on any one spot.

Additional "Touch" Exercises

Close your eyes, and either touch or stroke your face with the brush. Tell yourself whether you are going to touch or stroke your face with the brush before you do it. If you have someone at home to help you with the exercises, ask him or her to either touch or stroke your face with the brush.

For the first five or so tries, be sure that your partner tells you before the brush touches your face whether it will be a touch or a stroke.

Try keeping your eyes closed, and then let your partner either touch or stroke your face with the brush without telling you what to expect.

If you can easily tell a touch from a stroke, that's great. Remember to decrease the length of the stroke about a quarter of an inch every other day; this will make the task more difficult.

The length of the stroke should result in it being challenging (but not impossible) for you to tell the difference between a touch and a stroke. Remember also to use both side-to-side strokes and up-and-down strokes. If you have difficulty even with long strokes, do not become frustrated. Most individuals sense little change from day to day. It is important that you be patient and persistent.

You can practice the touch exercises as many times during the day as you wish. Looking in the mirror while you practice is very important. If you do not have a brush with you, simply use a light finger touch.

Level II Patient Instructions (5 to 9 weeks after surgery)

Basic Touch Exercises

Do the touch exercises with the brush at least three times a day for 2 to 3 minutes each time: in the morning, at midday, and in the evening. When you begin, look in the mirror and watch the movement.

1. At first, alternate stroking your face side to side or up and down.
2. As you do the exercises, vary where you make the strokes on your face.
3. When you begin the exercises, start the side-to-side exercise on one side of the face, and stroke across the entire region to the other side of the face. For example, move from the bottom of your ear across your upper lip to the bottom of your other ear.
4. When you stroke up and down, start on your neck, and go all the way up and down your face. For example, move from your neck all the way up the side of your face to the forehead, or start just below your eye and stroke down to your neck.
5. While doing the exercise, tell yourself that whatever sensation you feel is normal and expected.

Continued

6. Seeing the orientation of the stroke and the area of the face that you are touching reflected in the mirror and telling yourself that all of the sensations you feel are normal and expected is important.
7. Be sure to move the brush around on both sides of your face. Do not spend all your time on any one spot.

Additional Touch Exercises

Close your eyes. Before you stroke your face with the brush, tell yourself whether you are going to stroke your face side to side or up and down with the brush. If you have someone at home to help you with the exercises, for the first five or so tries, be sure your partner tells you before the brush touches your face whether it will be a side-to-side or up-and-down stroke. Next, try keeping your eyes closed, and let your partner do the exercise again without telling you what to expect.

If you can easily tell an up-and-down stroke from a side-to-side stroke, that's great! Remember to decrease the length of the stroke by about a quarter of an inch every other day; this will make the task more difficult. The length of the stroke should result in it being challenging (but not impossible) for you to tell the difference between an up-and-down stroke and a side-to-side stroke.

If you have difficulty even with long strokes, do not become frustrated. Most patients sense little change from day to day. It is important that you be patient and persistent.

You can practice the touch exercises as many times during the day as you wish. Looking in the mirror while you practice is very important. If you do not have a brush with you, simply use a light finger touch.

Do the touch exercises with the brush at least three times a day for 2 to 3 minutes each time: in the morning, at midday, and in the evening. When you begin, look in the mirror and watch the movement.

12 Orthognathic Surgery Treatment Planning

JEFFREY C. POSNICK, DMD, MD

Part I: The Importance of Proportions and Symmetry to Establish Ideal Facial Aesthetics
- Fundamental Concepts
- Evolution in Thinking
- Current Philosophy

Part II: Clinical Evaluation of the Patient with a Dentofacial Deformity
- Background
- Global Head and Neck Assessment: Seven Critical Aspects
- Detailed Maxillomandibular Surgical Planning: Eight Critical, Quantitative, To-the-Millimeter Decisions
- Conclusions

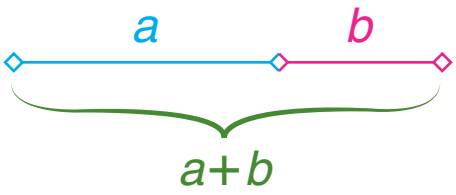
Part I: The Importance of Proportions and Symmetry to Establish Ideal Facial Aesthetics

Fundamental Concepts

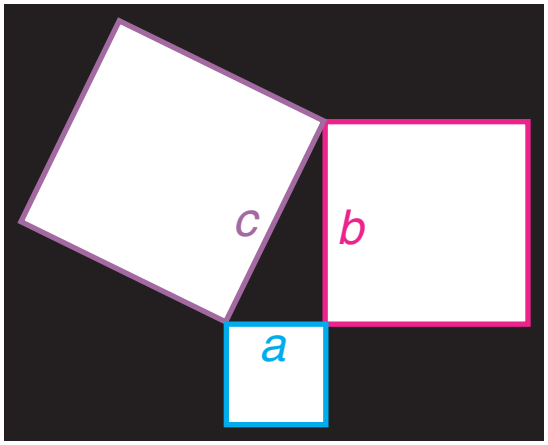
We use the word *proportion* to describe the comparative relationship between parts of things in an attempt to describe harmonious and disharmonious relationships between different parts of a whole.[13,14,49,92] The first clear and still unsurpassed definition of what has become known as the "golden ratio" was put into words by Euclid of Alexandria around 300 B.C.[5,29,42-44,61] Euclid is best known as the founder of geometry, which is a branch of mathematics that involves the use of deductive reasoning.[68] In the most pure way, Euclid defined a harmonious proportion derived from the simple division (sectioning) of a line into what he called its "extreme and mean ratio."[61] In Euclid's own words, "[a] straight line is said to have been cut in extreme and mean ratio when, as the whole line is to the greater segment, so is the greater to the lesser."[98,99] (Fig 12-1) This ratio was defined by Euclid as the *"golden ratio."* Interestingly, this ratio represents a never-ending (irrational) number 1.6180339887…. The common symbol for the golden ratio is the Greek letter tau (τ), the meaning of which is "the cut" or "the section." It was later renamed phi (Ψ) after the Greek sculptor Phidias, who was said to have employed it[61]; this is described in more detail later in this chapter.

A definition of the word *beauty* can be found in Webster's unabridged dictionary as "the quality which makes an object seem pleasing or satisfying in a certain way."[63] The golden ratio is said to be an important feature that is found in many classically beautiful works of art, architectural structures, objects designed for human use, the music of the great composers, and most of what is found in nature.[17,18,20,45,49,57,58,67,68] "Perfect" proportions are found throughout the art world and throughout the centuries. Objects of "classic" beauty and "attractive" forms found in nature consistently reveal the golden ratio.[40] However, an important question remains: "Does form really follow function?" Richard Buckminster Fuller (1895-1983), a great American architect and writer, once stated, "When I am working on a problem, I never think about beauty. I think only of how to solve the problem. But when I finish, if the solution is not beautiful, I know it is wrong."[61]

In their simplest form, attractive facial images—whether in drawings, in photographs, or in reality—seem to incorporate a *consistent symmetry of proportion*. It has been stated that most people have a common appreciation of what is attractive when they visualize it even if they cannot quite explain why. This has been demonstrated across cultures and throughout the ages, and it has been relatively consistent in art and photography.[6,19,27,32,48,53,54,63,77,81,80] A strict mathematical formula may not be required to define classic attractiveness, but the question remains: "Can the golden ratio (a mathematical formula) be found in these commonly agreed upon beautiful images?"



• **Figure 12-1** Golden ratio (section) of a straight line.



• **Figure 12-2** Pythagorean theorem as described through a triangle.

Evolution in Thinking

Pythagoras (570 B.C.-522 B.C.) coined the terms *philosophy,* defined as "a love of wisdom," and *mathematics,* defined as "that which is learned."[47] He described a *philosopher* as someone who "gives himself up to discovering the meaning and purpose of life itself—to uncover the secrets of nature."[100,42,61] Pythagoras and his followers (i.e., Pythagoreans) are best known for their role in the development of mathematics and the application of mathematic principles to the concept of *order in the world*. The Pythagorean theorem states that, in a right-angle triangle, the square of the hypotenuse (i.e., the side opposite the right angle) is equal to the sum of the squares of the other two sides; in other words, $a^2 + b^2 = c^2$ (Fig. 12-2).[9]

According to legend, Pythagoras discovered that musical notes could be translated into an orderly mathematical equation by observing a blacksmith at work. He thought that the sounds emanating from the blacksmith's anvils, when they were struck, were both beautiful and harmonious. By studying the blacksmith's tools, Pythagoras discovered that the emanating sounds were "simple ratios of each other and that one was half the size of the first and so on."[61,100] He then constructed metal bells with each sized in equal ratio to the next. When he struck the proportionately sized bells, harmonious tunes resulted in the same way that he had observed with the anvils. The harmony that resulted when striking the proportionately sized bells or anvils, according to Pythagoras, was beautiful.

• **Figure 12-3** *Doryphoros* by Polykleitos. *From http://en.wikipedia.org/wiki/File:Doryphoros_MAN_Napoli_Inv6011-2.jpg Photograph by Marie-Lan Nguyen. Creative Commons License: Attribution.*

Pythagoreans also believed that "harmony existed with the spheres of the planets and stars according to a similar strict mathematical equation and thus produced a similar "planetary symphony."[61,100] Pythagoras later discovered flaws in the purity of mathematics. He was the first to write of having knowledge of a number that is "neither a whole—nor a ratio of two whole numbers."[61,100] This discovery was said to have overwhelmed his perspective of a world based on the intrinsic properties of whole numbers and their ratios. He could not find a role for irrational numbers in this world.[44] Pythagoreans believed that the existence of such irrational numbers was so horrific that such numbers represented some sort of cosmic mistake and thus should be suppressed and kept secret.

Pythagoras and the Pythagorean school made a great impact in various fields, from sculpture to philosophy.[55] Polykleitos (450 B.C.) is a vivid example of the positive influence of Pythagoras' ideas. Polykleitos consciously created a new approach to sculpture that is immortalized in his treatise *Kanon* and visually depicted in his design of the male nude (also known as *Kanon*), which exemplified his aesthetic theories regarding the mathematical basis of artistic perfection.[69] His general artistic aims were clarity, balance, and completeness. The *Kanon*'s basic principles are represented in Polykleitos' best-known bronze sculptures, including *Doryphoros* (Fig 12-3); *Diadumenos* (Fig 12-4); and *Astragalizontes.* These sculptures are said to have a precise commensurability (i.e., "symmetria") of all of the parts with one another. The idea of "symmetria" comes from the Hippocratic principles of "equilibrium" and "rhythmos."[100] Polykleitos also said that "perfection comes about little by little through many numbers."[61,100] This meant that

• **Figure 12-4** *Diadumenos* by Polykleitos. *Image Copyright © The Metropolitan Museum of Art, Image source: Art Resource, NY.*

a statue should be composed of clearly definable parts, all of which are related to one another through a system of ideal mathematical proportions and balance. This was expressed in terms of the ratios established by Pythagoras, including in the perfect intervals of the musical scale: 1:2 (octave), 2:3 (harmonic fifth), and 3:4 (harmonic fourth).

The Polykleitos school continued after Polykleitos' death and included at least 20 sculptors and artisans through early 200 B.C. They were defined by their adherence to the *Kanon* and its *principles of balance and definition* (i.e., clarity in the separation and relationship of the parts to the whole). Polykleitos' students would think beyond sculpture in bronze; this included the work of Polykleitos' son, Polykleitos the Younger, whose architectural design of the great theater of Epidaurus was remarkable for its harmony and balance (Fig. 12-5).[100] Within the theater, the place for spectators was divided into two tiers: the first one had 34 rows of places, and the second one had 21 rows (i.e., 34/21 = 1.61…). The angle between the theatron and the scene divides the circumference of the basis of the amphitheater in a ratio of 1.618…. Interestingly, both of these meet the standards of the golden section, which was soon to be precisely and clearly defined by Euclid, as described later in this chapter.

Polykleitos' greatest work is said to be the sculpture *Doryphoros* (i.e., "spear-bearer"), which is considered one of the best-known sculptures of the classic era.[100] During the second century A.D., Galen would write about *Doryphoros* as the perfect visual expression of Greece's search for harmony and beauty, which is rendered in the perfectly proportioned sculpted male nude. Galen stated the following:

• **Figure 12-5** Theater of Epidaurus in Epidaurus, Greece. Copyright 2013 BootsnAll Travel Network, LLC. All Rights Reserved. http://www.greecelogue.com/the-ancient-theater-of-epidaurus.html.

> *Chrysippos [or Doryphoros, the spear-bearer] holds beauty to consist not in the commensurability or "symmetria" [i.e., proportions] of the constituent elements [of the body], but in the commensurability of the parts, such as that of finger to finger, and of all the fingers to the palm and wrist, and of those of the forearm, and of the forearm to the upper arm, and in fact, of everything to everything else, just as it is written in the Canon of Polyclitus [Polykleitos]. For having taught us in that work all the proportions of the body, Polyclitus supported his treatise with a work: he made a statue according to the tenets of his treatise and called the statue, like the work, the "Canon" [i.e.,* Kanon*].*[61,100]

A contemporary of Polykleitos was Phidias (480 B.C.),[100] who is regarded as one of the greatest sculptors of bronze, gold, and ivory from Greek antiquity. Phidias' statue of *Zeus at Olympia* was considered one of the seven manmade wonders of the Ancient World (Fig. 12-6). He also created the statue of the *Goddess Athena* on the Athenian Acropolis (Fig. 12-7) as well as the *Athena Promachos* (i.e., a bronze statue of Athena) adjacent to the entrance of the Acropolis in Athens (Fig. 12-8). The influence of Pythagorean mathematics, the *Kanon* (i.e., the relationship of the parts to the whole), and the golden ratio (although not spoken of as a specific number) are clearly represented in all of Phidias' works.

Pythagoras' writings also influenced Plato (428 B.C.-337 B.C.), who is considered one of the most extraordinary minds of Ancient Greece and of Western civilization in general.[100] His text, the *Republic,* states that mathematics is an absolute must for the education of all state leaders and philosophers (Fig. 12-9). Plato was intrigued by the *five regular polyhedrons* that are now considered the *Platonic solids* (Fig. 12-10). He used their design to emphasize the importance of proportions for the achievement of "ideal" beauty. His thinking must have also been greatly influenced by Polykleitos' sculptures and written words in the *Kanon.* Plato is quoted as follows:

• **Figure 12-6** Statue of Zeus at Olympia by Phidias.

• **Figure 12-8** Statue of the Goddess Athena at the entrance of the Athenian Acropolis by Phidias. *From http://en.wikipedia.org/wiki/File:NAMA_Ath%C3%A9na_Varvakeion.jpg Photograph by Marsyas. Creative Commons License: Attribution.*

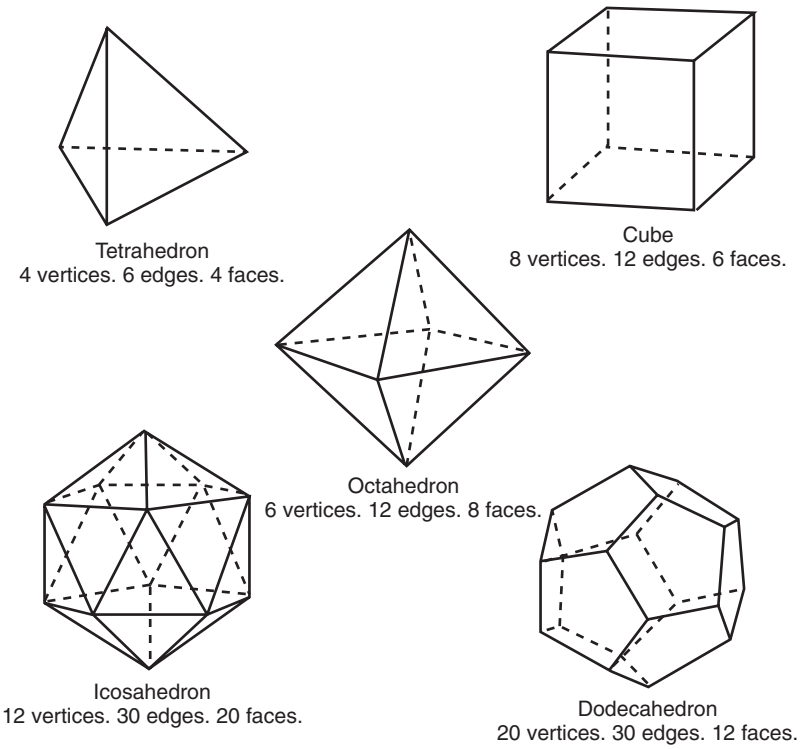
Two parts or values cannot be satisfactorily connected among themselves without a third part; the most beautiful link is that, which together with two initial values gives the perfect unit. It is reached in the best way by proportion [analogy], in which among three numbers, planes or bodies, the mean one so concerns to the second one, as the first one to the mean one, and also the second one to the mean one as the mean one to the first one. This implies, that the mean one can exchange the first one and the second one, the first one and the second one can exchange the mean one and all things together thus makes an indissolvable unit.[61,100]

Plato's favored student Aristotle (384 B.C.-?) was able to take Pythagorean ideas and the *Kanon* of Polykleitos a step further forward when he wrote that *the main requirements of beauty include order, proportionality, and control of sizes* (i.e., the relationship of the parts to each other).[100] *Order*



• **Figure 12-10** The five Platonic solids described by Euclid.

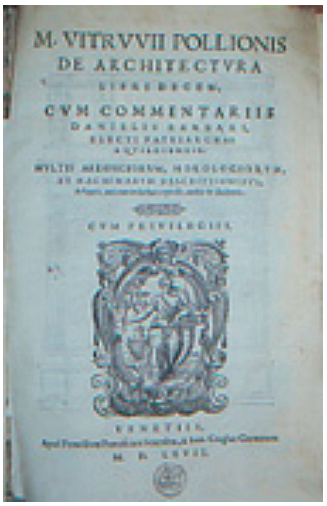
was said to arise "when between parts of the whole there are definite ratios in proportions."[61,100] In music, for example, Aristotle recognized the octave as the most beautiful consonance when taking into consideration that the number of oscillations between the basic tone and the octave can be expressed by the first numbers of a natural series: 1 : 2. He also had the opinion that *rhythmic relations* of a poetic verse should be based on small numerical ratios to reach a beautiful impression.[41] Like Plato, Aristotle believed that *beauty was commensurate of the separate parts to the whole*.

The young Alexander the Great of Macedonia (Fig. 12-11) succeeded to the throne after his father's assassination (336 B.C.). He went on to conquer most of Asia Minor, Syria, Egypt, and Babylon, and he then founded the City of Alexandria near the mouth of the Nile. Alexandria developed into the intellectual center of the hemisphere, and it included a library that is said to have held more than 700,000 books. The first group of scholars at the center included the young *Euclid* (300 B.C.), who authored a complete text about the history of mathematics that included many of his own original ideas (Fig. 12-12). The *Elements* was a 13-volume work on geometry and number theory.[43] Each book contained a number of theorems (i.e., from 10 to 100) that follow a series of definitions. Scholars believe that the *Elements* is primarily a collection of theorems described by other mathematicians that was then supplemented by at least some original work by Euclid. Proclus, a Greek mathematician who lived several centuries after Euclid, wrote the following in his commentary about the *Elements*: "Euclid, who put together the *Elements*, collecting many of Eudoxus' theorems, perfecting many of

• **Figure 12-11** Sculpture of Alexander the Great of Macedonia. *From http://en.wikipedia.org/wiki.File:Alexander1256.jpg*

Theaetetus, and also bringing to irrefutable demonstration the things which were only somewhat loosely proven by his predecessors."[5] For example, Pythagoras was probably the source of most of Books 1 and 2; the ideas of Hippocrates were found in Book 3, and those of Eudoxus were in Book 5; Books 4, 6, 11, and 12 probably came from other Pythagorean or Athenian mathematicians. Euclid is credited with replacing Fallacious' proofs with his own more rigorous versions. Most of the definitions, postulates, and axioms within the *Elements* date back to Plato. Euclid also authored

• **Figure 12-12** The 13-volume *Elements* text written by Euclid.



• **Figure 12-13** The 10-volume *De Architectura* text written by Marcus Vitruvius Polio.

almost a dozen other books that covered topics from music to mechanics and optics. His book *Optics* contains some of the earliest studies of perspective. Interestingly, until the 20th century, Euclid's *Elements* remained second only to the Bible with regard to the number of books sold worldwide. Euclid's textbook, through various translations, has remained actively referenced for more than 2300 years.

The golden ratio or golden section appears in the *Elements,* primarily in relation to proportions in Book 6: *On Divisions of Figures.*[43] Book 6 survives only partially in an Arabic translation, and it discusses the division of geometric figures into two or more parts or into parts in given ratios. It is likely that Euclid's primary interest in the golden ratio was as a means of geometric interpretation of the construction of the five Platonic solids. This discussion is also found in Book 13, which constructs the five regular Platonic solids that are inscribed within a sphere. Euclid calculated the ratio of their edges to the radius of the sphere and proved that there are no other regular solids to be found. Curiosity about the structure and design of these Platonic Solids were of much interest to Ancient Greek intellectuals.[47] In addition, throughout the *Elements,* Euclid described several theorems and their proofs, which also employed the golden ratio. Although no documentation has been found to confirm Euclid's knowledge of Polykleitos' *Kanon* or Aristotle's stated *requirements of beauty (i.e., order, proportionality, and control of sizes),* it is almost inconceivable that these ideas did not influence him.

Marcus Vitruvius Polio (80 B.C.-15 B.C.) came two centuries after Euclid; he was a Roman writer, architect, and engineer. At one point, he even served as Chief of Artillery for the Roman Army. His written work *De Architectura,* a 10-volume treatise on architecture, is not just remarkable for its originality and contents but also for being the only surviving major book about architecture from classic antiquity (Fig. 12-13). This treatise indicates a mastery of architecture and engineering, and it crystallizes the importance of precise proportions as a fundamental component of beauty in the human form. Interestingly, in the records that remain, no mention is made by Vitruvius of Pythagoras, Polykleitos, or Euclid. This lack of acknowledgement by Vitruvius is striking in its absence; thus, it likely represents lost documents rather than a lack of awareness.

Fortunately, Vitruvius' treatise would later be rediscovered by the Florentine humanist Poggio Bracciolini (1414). It was Leon Battista Alberti (1404-1472) who then revitalized Vitruvius' works by writing a widely read seminal treatise on architecture, *De Re Aedificatoria,* which was published in 1450.[35] During the High Italian Renaissance, this volume had a great influence on artists, scholars, and architects, including Leonardo da Vinci (1452-1519) and Michelangelo (1475-1564).[72] Vitruvius is most remembered for his basic assertion that a structure must exhibit the three qualities of *firmitas, utilitas,* and *venustas:* it must be strong (durable), useful, and beautiful. According to Vitruvius, architecture is an imitation of nature: "As birds and bees built their nests, so humans construct housing, from natural materials that give them shelter against the elements."[61] When perfecting the art of building, ancient greeks designed and defined the three architectural orders: *Doric* (Fig. 12-14), *Ionic* (Fig. 12-15), and *Corinthian* (Fig. 12-16).[100] These architectural orders gave the Ancient Greek buildings a sense of proportion and continuity that was believed to be as important as the proportions of the greatest known work of art: the human body. This led Vitruvius to define the proportions of the human body in words that would later be illustrated by Leonardo da Vinci's *Vitruvian Man* (1437; Fig. 12-17). The human body as described by Vitruvius was inscribed in a circle and in a square. These are considered the fundamental geometric patterns of the cosmic order.[102]

After the destruction of the great Alexandrian library—first by Roman, then by Christian, and finally by Muslim groups—the center of study came to an end (529 A.D.). With the ascendancy of Islam and the initial attempts of Islamic groups to destroy everything "non-Islam," many of the earlier Greek and Roman literary works were lost as the Arab world became the dominant center for intellectual study. Abu Kmil Shuja (850-930), who was known as *al-Hasib al-Misri* (translated as "The Calculator from Egypt"), shared his rediscovery of Euclid's works through Arabic translations.

Abu Kmil's books would later serve as a basis for Leonardo of Pisa's further understanding of Euclid's geometric principles. Leonardo of Pisa (1170-1250) was also known as Fibonacci, Leonardo Bonacci, Leonardo Pisano Bogollo, and Leonardo Fibonacci; he was considered the most talented mathematician of the late middle ages.[25] He is best remembered by the modern world for spreading knowledge of the Hindu-Arabic numeral system (i.e., digits 0 through 9) in Europe; this was primarily done through publication during the earlier 13th century of the *Book of Calculations* or *Liber Abaci*.[97] His second contribution was the recognition of a number sequence that became known as the *Fibonacci numbers* (Fig 12-18). Within the *Liber Abaci*, Fibonacci posed and solved a classic problem involving the growth of a hypothetical population of rabbits that was based on idealized assumptions (Fig 12-19). The solution was a sequence of numbers that was later named after Fibonacci. Although this number sequence was known to Indian mathematicians as early as the sixth century, it was Fibonacci's *Liber Abaci* that introduced it to the West.[101] In the sequence of the Fibonacci numbers, each number is the sum of the previous

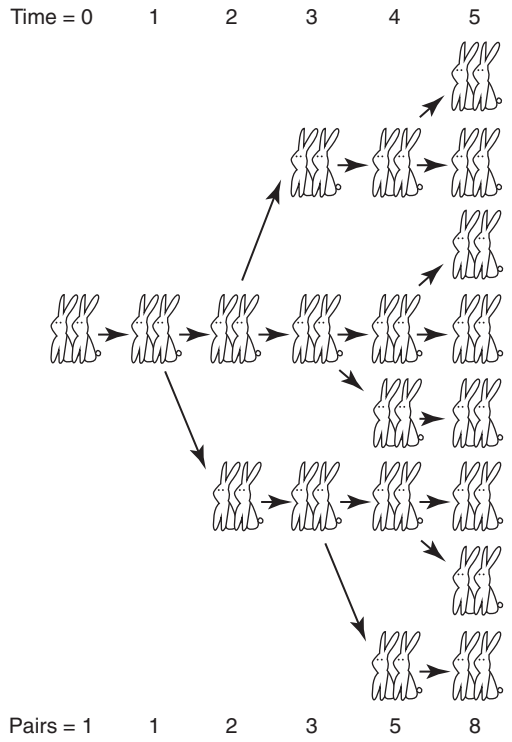
• **Figure 12-18** Fibonacci numbers.

two numbers, starting with 0 and 1. Thus, the sequence begins 0, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, and so on. Interestingly, the higher up in the sequence, the closer two consecutive numbers in the sequence—when divided by each other—will approach the golden ratio of approximately 1 : 1.618 or 0.618 : 1. The sequence of the Fibonacci numbers and their relative ratios have been found with consistency in nature, art, and classic objects of beauty. They would soon be recognized and used by the Renaissance painters.

The Fibonacci numbers and the golden ratio are found in the most basic forms in nature.[25] For example, spirals arise from a property of growth called "self-similarity" (i.e., the tendency to grow in size but to maintain the same shape). This is seen in the simplest of natural forms: the *shell of the chambered nautilus*. As the nautilus outgrows each chamber, it builds a new chamber for itself, but this always has the same shape (Fig. 12-20). If the nautilus lives a long life, it will spiral around and around, growing even larger but always looking exactly the same at every scale. Interestingly, by using the Fibonacci sequence of numbers, you can build a nautilus that is based on squares by starting with a square of size 1 and successively building new "rooms" with sizes that correspond with the Fibonacci sequence.[39] Running through the centers of the squares, a smooth curve can be drawn that corresponds to the nautilus spiral (see Fig. 12-20, *B*). This self-similar curve, which keeps its shape at every scale, is called *equiangular* because a radial line from the center always makes the same angle to the curve. This curve was also known to Archimedes of Ancient

Greece, who—philosophically and religiously—thought of this curve as both spiraling inward forever as well as spiraling outward forever. Euclid's golden ratio mathematically describes this finding both in nature and in the Fibonacci numbers.

Euclid's ideas have had an enormous impact throughout the centuries,[5] first on the medieval Italian philosopher St. Thomas Aquinas (1225-1274) and then on the Renaissance Italian architect L.B. Alberti (1404-1472).[72] Aquinas captured the fundamental relationship between beauty and mathematics when he stated that *"humans seem to react with a sense of pleasure to forms that possess certain symmetries [proportions] and obey certain mathematical rules."*[35,61]



• **Figure 12-19** Fibonacci numbers as described through breeding rabbits. The sequence 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, 233, and so on—in which each term (starting with the third) is equal to the sum of the two preceding terms—was appropriately dubbed the *Fibonacci numbers* during the 19th century by the French mathematician Edouard Lucas (1842-1891).

Leon Battista Alberti was an author, artist, architecture, poet, priest, linguist, philosopher, cryptographer, and general Renaissance humanist. Alberti regarded mathematics (as summarized by Euclid) to be the common ground of the arts and the sciences. For Alberti, *beauty was "the harmony of all parts in relation to one another."* He stated that "this concord is realized in a particular number, proportion and arrangement demanded by harmony."[35,61] Alberti's thoughts on harmony were referenced back to Pythagoras and Euclid, but he set them in a fresh context. He studied Ancient Roman sites, ruins, and objects and made detailed observations that are cataloged in his *Ten Books of Architecture (De Re Aedificatoria),* which was published in 1450 A.D. His writings were patterned after the *De Architectura* by Vitruvius (46 B.C.-30 B.C.) and covered a wide range of subjects, from history to town planning to engineering to the philosophy of beauty.

Three Renaissance genius mathematicians and artists were clearly influenced by Euclid's ideas[72]: Piero della Francesca (1415-1492), Leonardo da Vinci (1452-1519), and Luca Pacioli (1446-1517). Piero della Francesca was known as a mathematician, a geometer, and an artist. His painting was characterized by its serene humanism and its use of geometric forms, particularly in relation to perspective and foreshortening (Fig. 12-21). It is known that he was at least acquainted with Leon Battista Alberti's mathematical and architectural work and that he would also have a significant influence on Luca Pacioli's thinking.[71] Three important mathematical treatises were written by Piero: *Abacus Treatise (Trattato d'Abaco)*; *Short Book on the Five Regular Solids (Libellius de Quinque Corporibus Regularibus)*; and *Perspective on Painting (De Prospectiva Pingendi)*. The subjects covered in these writings include mathematics, algebra, geometry, and innovative work on both solid geometry and perspective. Much of Piero's work would later be rewritten

• **Figure 12-22** Self-portrait by Pacioli.

by others, including Luca Pacioli.[71] Piero's work on solid geometry appears in Pacioli's *De Divina Proportione*, which is believed to have been illustrated by Leonardo da Vinci. Piero's *Perspective on Painting (De Prospectiva Pingendi)* clearly refers to Euclid's *Elements* and *Optics*. Piero used Euclid's written works to demonstrate that, to achieve perspective in a painting, the artist must rely on the scientific basis of visual perception. Piero's treatise *De Prospectiva Pingendi* became the standard manual of the day for artists who attempted to paint plain figures and solids.

Luca Pacioli (Fra Luca Bartolomeo de Pacioli) lived from 1446 to 1517. He was a Franciscan friar and an Italian mathematician.[71] He later collaborated with Leonardo da Vinci, and he also made seminal contributions to the field that is now known as accounting. In 1494, his first book—*Summa di Aritmetica, Geometria, Proporzioni e Proporzionalità* was published in Venice. This text compiled the knowledge of the time related to arithmetic, algebra, geometry, and trigonometry. Pacioli identified Fibonacci (Leonardo of Pisa) as the primary source for his basic facts. Several years later, he met, collaborated with, lived with, and taught mathematics to Leonardo da Vinci. Pacioli also completed the three-volume treatise *The Divine Proportion (De Divina Proportione),* which applies to geometrical proportions, letters, and architecture constructions. The original manuscript, which was written around 1496 to 1498, is preserved in Milan; it was published in Venice in 1509.[71] Within the text, Pacioli lists five reasons why a more appropriate name for Euclid's golden ratio would be *"the divine proportion."* References and analogies to the church and godliness clarify Pacioli's *belief that the divine proportion is spiritual and universal*. He was also interested in the process of painting, and he emphasized his desire to reveal the secret to the creation of harmonic forms through the use of the golden ratio (or the divine proportion). Pacioli used the square and the compass (which are clearly visible in the background of his well-known self-portrait) to both analyze the works of others and to help artists achieve divine proportions in their paintings (Fig. 12-22). It is believed that Pacioli invited Leonardo da Vinci to provide 60 illustrations, primarily of solid objects, to clarify the importance of the divine proportion. (Fig. 12-23). Leonardo's drawings are the first illustrations of geometric figures in the dual state of skeletonic (vacuum) and solid (solidum) (Fig. 12-24). This allowed for a distinct interpretation between front and back. Pacioli wrote of da Vinci's contributions to society by stating that "he is the most excellent painter in perspective, architect, musician and man endowed with all virtues."[71] Pacioli's text largely restates the earlier published work of the Roman architect Marcus Vitruvius Polio.[5] Within the text, Pacioli states the following:

> *"The ancients, having taken into consideration the rigorous construction of the human body, elaborated all their works, especially their holy temples, according to these proportions; for they found here the two principal figures without which no project is possible: the perfection of the circle, the principle of all regular bodies, and the equilateral square."*

It is clear from a woodcut sketch included in *De Divina Proportione* (1509) that Luca Pacioli understood the importance of the golden ratio as it applies to the human face (Fig. 12-25). It is also believed that, at the request of Pacioli, Leonardo da Vinci took Vitruvius' written words and drew them out in a diagram that he called *Vitruvian Man* (1487; see Fig 12-17).[61] The image depicts a male figure in two superimposed positions with his arms and legs apart and simultaneously inscribed in a circle and a square. The

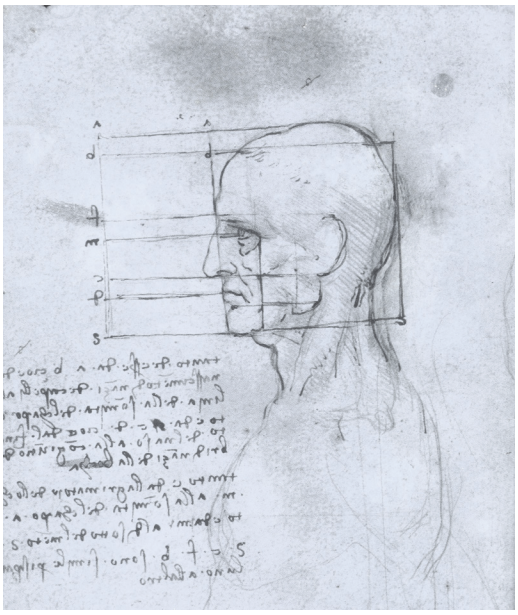
illustrated interpretation of Vitruvius' words is sometimes also called the *Canon of Proportions;* the original drawing is stored in the Galleria dell'Accademia in Venice, Italy. It is known that *Vitruvius described the human figure as being the principal source of correct proportions and symmetry among the classic orders of architecture*. da Vinci's *Vitruvian Man* beautifully demonstrates the blend of art and science envisioned by intellectuals during the renaissance, and it provides a clear understanding of the artist's keen interest in the proportions of the human form. Like Plato, da Vinci believed the workings of the human body to be an analogy of the workings of the universe. According to Leonardo himself, in a note that accompanied the drawing, "it was made as a study of the proportions of the male human body as described by Vitruvius" ("Palmus autem habet quattuor digitos").[61,72] Vitruvius' words, which Leonardo attempted to draw out in pen and ink on paper, are found in Vitruvius' *De Architectura* 3.1.2-3, which reads as follows:

> *For the human body is so designed by nature that the face, from the chin to the top of the forehead and the lowest roots of the hair, is a tenth part of the whole height; the open hand from the wrist to the tip of the middle finger is just the same; the head from the chin to the crown is an eighth, and with the neck and shoulder from the top of the breasts to the lowest roots of the hair is a sixth; from the middle of the breasts to the summit of the crown is a fourth. If we take the height of the face itself, the distance from the bottom of the chin to the underside of the nostrils is one-third of it; the nose from the underside of the nostrils to a line between the eyebrows is the same; from there to the lowest roots of the hair is also a third, comprising the forehead. The length of the foot is one-sixth of the height of the body; of the forearm, one-fourth; and the breadth of the breasts is also one-fourth. The other members, too, have their own symmetrical proportions,*

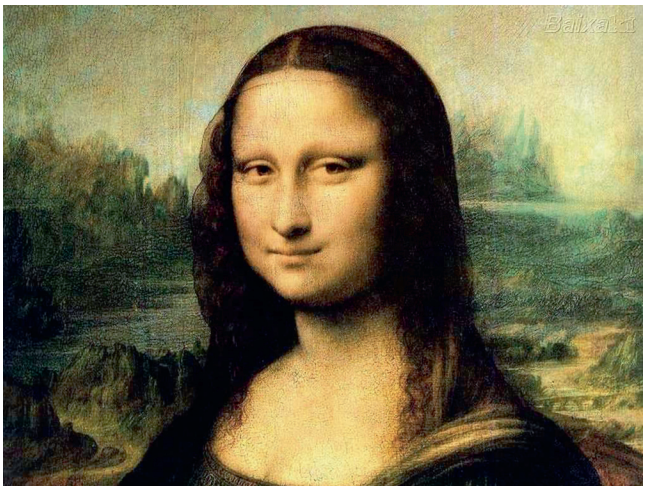
and it was by employing them that the famous painters and sculptors of antiquity attained to great and endless renown. Similarly, in the members of a temple, there ought to be the greatest harmony in the symmetrical relations of the different parts to the general magnitude of the whole. Then again, in the human body, the central point is naturally the navel. For if a man is placed flat on his back, with his hands and feet extended, and a pair of compasses centered at the navel, the fingers and the toes of his two hands and feet will touch the circumference of a circle described therefrom. Just as the human body yields a circular outline, so too a square figure may be found from it. For if we measure the distance from the soles of the feet to the top of the head, and then apply that measure to the outstretched arms, the breadth will be found to be the same as the height, as in the case of plain surfaces which are perfectly squared.[61,72]

For some scholars and artists of the High Italian Renaissance, the golden ratio was elevated from a simple mathematical formula to become a way of explaining natural phenomena and a tool to be used in the painting of objects and human forms.[66,93] By the mid 1400s, advances in technology allowed artists to use lenses, concave mirrors, and other methods to help them to create realistic-looking paintings. Many of today's critics believe that, simply by using their innate aesthetic sense, talented artists, architects and designers of that time period created art, built structures, and designed objects that closely approximate the golden ratio.[46] Skeptics often claim that the most attractive and harmonious objects were methodically designed by their artists to adhere to the golden ratio measurements; they also believe that many of the great artists' designs were simply superimposed on laid-out golden ratios. Interestingly, many other scholars deny that the Greeks (e.g., Euclid) made any direct aesthetic associations with the golden ratio. Thus, some questions remain unanswered: *Throughout antiquity and during the Renaissance, did artists consciously use the golden ratio as part of their technique? Did they model their work on precise mathematical dimensions, or was their aesthetic and artistic sense the guiding force that inevitably closely approximated the golden ratio?*

The analysis of Leonardo's drawing entitled *A Head of an Old Man* (Fig. 12-26) leaves little doubt that he was, at the very least, intrigued by various proportions of the face. This drawing shows how Leonardo used standard rectangles to determine dimensions in his paintings. Because classic art requires "harmony" and because we know that Leonardo collaborated with Pacioli and that he was believed to be the illustrator of *Divine Proportions*, Leonardo's use of the golden ratio in his paintings would be an obvious extension of his mathematic knowledge and artistic principles. Most of today's art critics place Leonardo's *Mona Lisa* on a short list of the most beautiful faces ever painted (Fig. 12-27). Debate continues regarding Leonardo's conscious use of the golden ratio in this well-known work. Interestingly, da Vinci is said to have revised the *Mona Lisa* for more than 10 years before his death without ever fully finishing the work to his own satisfaction.

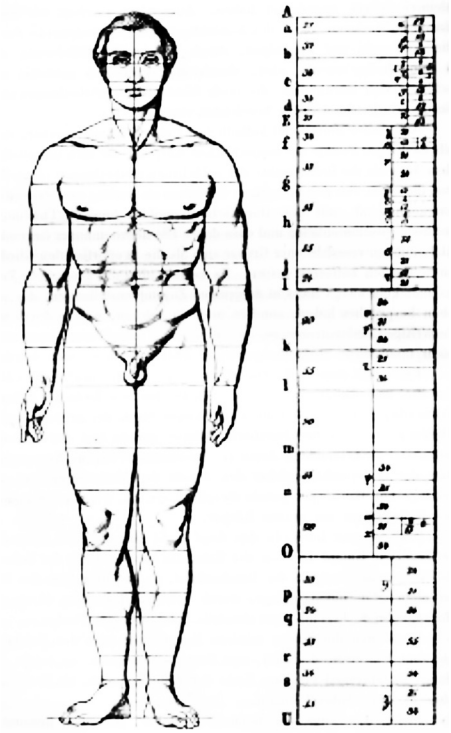


• **Figure 12-26** *Head of an Old Man* by Leonard da Vinci, confirming the golden ratio. *From Royal Library, Windsor Castle, Windsor, Great Britain. Photo Credit: Alinari/Art Resource, NY.*



• **Figure 12-27** *Mona Lisa* by Leonardo da Vinci.

After Leonardo, the golden ratio as an artistic principle likely fell from favor. To my knowledge, no prominent philosopher or artist was known to have actively used the golden ratio again until Adolf Zeising (1810-1876).[105] Zeising was formally trained in psychology, mathematics, and philosophy. He found the golden ratio expressed in all things, including in the skeletons of animals and the branching of their veins and nerves (Fig. 12-28). In connection with his theory involving golden-ratio–based human body proportions, Zeising (1854) wrote what he called the "universal law of proportions," "in which is contained the ground-principle of all formative striving for beauty and completeness in the realms of both nature and art, and

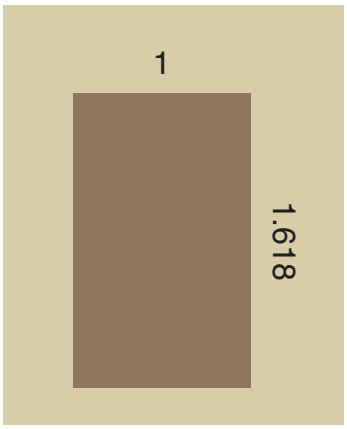


• **Figure 12-28** *Human Ratio* by Zeising, confirming the golden ratio.

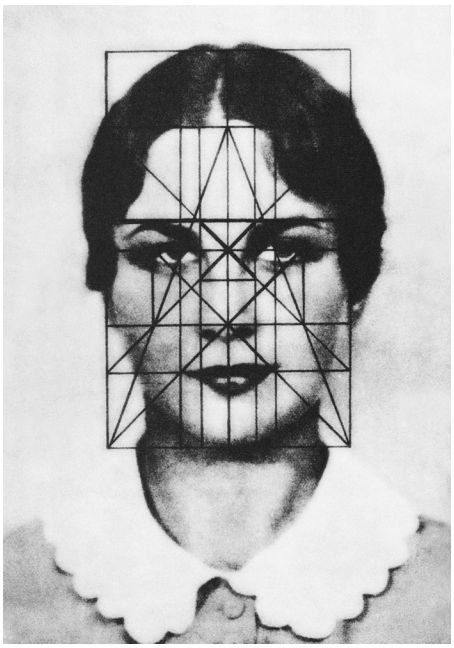
which permeates, as a paramount spiritual ideal, all structures, forms and proportions, whether cosmic or individual, organic or inorganic, acoustic or optical; which finds its fullest realization, however, in the human form."[34]

The famous German psychologist, Gustav Fechner, was inspired by Adolf Zeising's book *Der Goldene Schnitt* and began a series of inquiries to see if the golden rectangle had psychological aesthetic impact.[34] A golden rectangle is one with side lengths that reflect the golden ratio. A distinctive feature of this shape is that, when a square section is removed, the remainder creates another golden rectangle. In other words, it has the same proportions as the first. Another section can be removed infinitely, with the same results. Fechner's work was published in 1876. He made thousands of measurements of commonly seen rectangles (e.g., writing pads, books, playing cards, windows) and found that most were close to phi (Fig. 12-29). He also tested people's preferences and found that most people prefer the shape of the golden rectangle. Fechner's experiments were repeated and validated by others, including Witmar (1894), Lalo (1908), and Thorndike (1917).[34]

By the late 1800s, knowledge of and the conscious use of the golden ratio by painters, architects, and designers was well documented.[34] There are clear examples where these professionals have modeled their end products to conform with Euclid's golden ratio. In 1946 in *The Geometry of Art and Life,* Matila Ghyka presented an analysis of the face of the tennis champion Helen Wills.[34] He made several measurements of Wills' face, all of which were shown to be consistent with the divine proportion (Fig. 12-30). More recent examples include Salvador Dali's use of the golden



• **Figure 12-29** *Ideal Rectangle* by Fechner, confirming the golden ratio.



• **Figure 12-30** Facial proportions of Helen Wills by Matila Ghyk, confirming the golden ratio. From Matila Ghyk: *The Geometry of Art and Life,* 1946, Kessinger Publishing, Oct. 30, 2004, p. 102.

ratio in his masterpiece *The Sacrament of the Last Supper* (1955; Fig. 12-31) and the experimental piece of music *Binary Universe* (2006) by Brian Transeau. A strong advocate for the conscious application of the golden ratio to art, the design of objects, and architecture was *Le Corbusier* (1887-1965).[32,59] His legacy remains one of the most influential in modern architecture. He developed an intense interest in proportional systems and their role in all forms of aesthetics. Le Corbusier's fascination with the importance of the golden ratio in aesthetics centered around his belief that basic forms and structures are the underpinning of natural phenomenon. He developed what he called the *Modulor* in the tradition of Vitruvius with the intention of improving both the appearance and function of all manmade objects and architecture (Fig. 12-32).[59] He was also a strong believer in the idea that ideal harmony in music (as stated

• **Figure 12-31** *The Sacrament of the Last Supper* by Salvador Dali, confirming the golden ratio. *Copyright Salvador Dali, Fundacio Gala-Salvador Dali, Artists Rights Society (ARS), New York, 2013.*

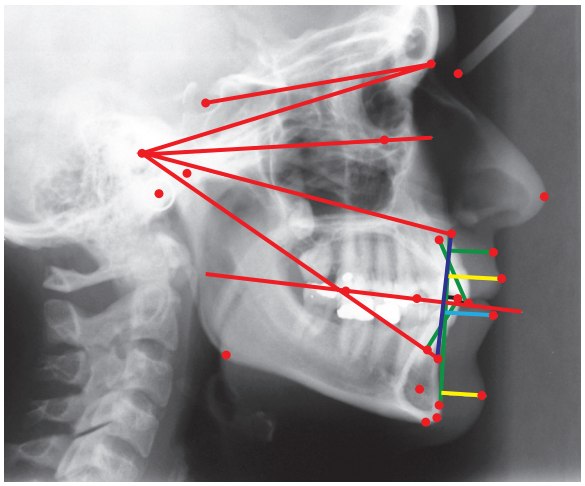
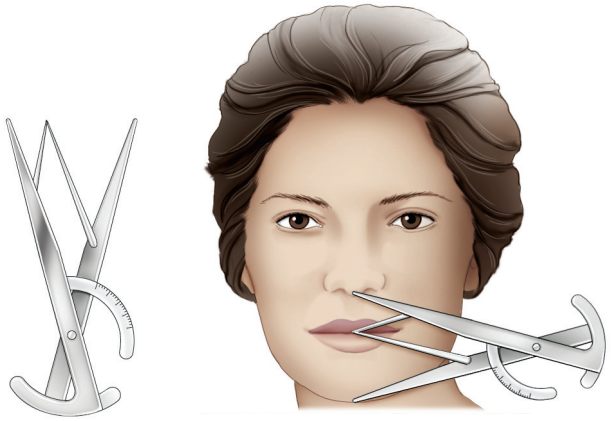
by Pythagoras) could only be achieved through the application of the golden ratio to numbers.

Current Philosophy

From Pythagoras, Polykleitos, Plato, Aristotle, Euclid, Vitruvius, Galen, Fibonacci, Piero, da Vinci, and Pacioli as well as the more recent Le Corbusier and all of their disciples for more than 2.5 millennia, we have learned that the proportions of the parts to the whole affect the observers' impression of beauty and attractiveness.[1,3,7,23,26,29,36,56,62,82,96] From the premier artists, architects, and designers throughout the centuries, we know that mirror-image symmetry and the harmony of proportions matter when judging facial aesthetics. They have also shown by example that the precise—even to the millimeter—achievement of an exacting mathematical ratio is not sufficient or even preferred for



• **Figure 12-33** Skeletal proportions according to cephalometric analysis.



• **Figure 12-34** Human face with use of the Rickett's divider, confirming the golden ratio.

the creation of the most important end products; rather, an approximation of the golden ratio is.

In the realm of facial aesthetics and reconstructive surgery, clinicians from all involved fields have from time to time attempted to match facial aesthetics to a strict mathematical model (e.g., normative cephalometric measurements) without always considering individual biologic variations and aesthetic nuances* (Fig. 12-33). When doing so, they have often fallen short of their objective. In 1984, Ricketts reported about a significant number of golden proportions when analyzing the facial skeleton and overlying soft tissues.[83-91] He was a strong advocate of the use of these divine proportions as a guide for planning the correction of dentofacial deformities via orthognathic surgery (Fig. 12-34). The validity of Ricketts' approach to facial analysis for the correction of jaw deformities has been questioned by some while supported by most.[8,12,15,30,50,73,74,75,76,94] For the clinician who is asked to correct a congenital or developmental craniofacial or

*2, 4, 10, 11, 16, 21, 22, 24, 28, 31, 33, 37, 38, 51, 52, 60, 64, 65, 70, 78, 79, 95, 103, 104, 108, 153, 177, 200, 241, 246

maxillofacial deformity, attention is directed to both form and function. As R. Buckminster Fuller stated, "rarely are the two objectives divergent."[61] For the achievement of a harmonious face, attention is directed toward the practical objectives of improving the upper airway and the occlusion, which will affect speech, swallowing, chewing, and breathing. Facial aesthetic perfection is not a specific millimeter distance or degree of angulation but rather a visual impression at conversational distance in three-dimensional life. At the same time, neither divine proportions nor biologic realities and the patient's personal preferences can be ignored throughout the process.

The rediscovery of the importance of achieving an approximation of Euclidean proportions and mirror-image symmetry as a treatment objective in the correction of dentofacial deformities remains an essential step in the education of all students of the human face.

Part II: Clinical Evaluation of the Patient with a Dentofacial Deformity

Background

In the correction of a dentofacial deformity, the clinician's aesthetic sense and knowledge of patient-specific biologic and psychosocial factors must be condensed into precise millimeter measurements and angular changes that are then accomplished on the surgically sectioned (osteotomized) maxilla, mandible, and chin region with a goal of establishing *Euclidean facial proportions* and *improved function*.* Although there is no singular normative table of numbers or a formula that can be relied on to direct the surgeon to the *golden ratio,* a methodical approach is nevertheless required. The clinician's vision is based on 1) fundamental aesthetic principles 2) the biologic realities of the tissues 3) patient-specific dysfunctions (e.g., chewing, swallowing, speech articulation, breathing, lip closure/posture) and 4) individual treatment preferences (e.g., timing, techniques, extent of intervention).† It is expected that a degree of uneasiness about the end result will be felt by both the operating surgeon as well as the patient and his or her family during this process. With clinician experience, this creative tension for the surgeon and the uncertainty of the patient and his or her family are reduced; however, these can never be fully alleviated before surgery.

At the time of the preoperative, direct, face-to-face planning examination of the patient by the operating surgeon, several evaluations will have already been carried out.[118,136,193,199,197,247] A review of relevant medical data in combination with facial photographic, radiographic, and dental analysis should be fresh in the surgeon's mind. The patient's facial structures are examined while he or she is upright and sitting in the *natural head position* (NHP). This is considered the most rational, physiologic, and anatomic orientation of the head and neck for the evaluation of the face, jaws, and teeth.* This is generally not the head and neck position in which the patient with a dentofacial deformity will naturally relax. Rather, the clinician must place the patient in the NHP. The teeth are also placed in *centric relation or with a normal freeway space,* and the *lips are relaxed* (i.e., not pursed together). The clinician then observes the patient three dimensionally at different angles in both repose and with dynamic facial expressions. *It is from the NHP that the surgeon makes crucial decisions regarding what facial features are abnormal and the extent of required surgical reorientation*.

Global Head and Neck Assessment: Seven Critical Aspects

1. *Quality of the overlying soft-tissue envelope of the head and neck.* The surgeon must recognize distortions of the soft-tissue envelope that will self-correct after the skeleton is reconstructed versus intrinsic soft-tissue malformations and deformities that will not (e.g., hypoplasia, hyperplasia, effects of trauma and aging).
2. *Symmetry and harmony of the upper facial skeleton (i.e., cranial vault, orbits, nasofrontal process, and zygomatic arches).* Although most individuals with dentofacial deformities have relatively normal upper facial skeletons, some do not (i.e., those with hemifacial microsomia or Treacher Collins syndrome).
3. *Morphology of unique aesthetic units of the face (e.g., external nose, external ears, periorbital soft tissues).*
4. *History of temporomandibular joint symptoms and signs and the documentation of any limitations in the mandibular range of motion.*
5. *History of cervical spine symptoms and signs and the documentation of the safe neck range of motion.*
6. *Symmetry and harmony of the lower facial skeleton (i.e., maxilla, mandible, and chin region).* The patient with a dentofacial deformity will have significant variations from normal in this region of the craniofacial skeleton.
7. *Dental rehabilitative needs (i.e., restorative and periodontal) as well as orthodontic aspects.*

Evaluation of the Overlying Soft-Tissue Envelope

An individual with a routine developmental jaw disproportion will generally have a normal overlying soft-tissue envelope that is simply distorted by the underlying skeletal disharmony. Alternatively, normal variations in the

*107, 111, 112, 122, 125, 138, 139, 161, 162, 166, 206, 207, 210, 215, 219, 223, 228, 229, 240, 248, 249

†114, 115, 116, 123, 127, 128, 129, 143, 144-150, 158, 174, 186, 189-191, 201-204, 208, 211, 222

*24, 124, 126, 133-135, 151, 168, 172, 171, 177, 181, 180, 184, 185, 225-227, 234, 238, 239, 243

thickness and quality of the skin, density of sweat glands, fat distribution, and degree of pigmentation are to be expected.

An example of soft-tissue distortion (not deformity) is seen with maxillomandibular deficiency (see Chapter 23). The impression of "chubby cheeks" and excess fat in the neck is typical. With maxillomandibular (skeletal) advancement and vertical lengthening, the normal facial contours and curvatures will be restored.

There are exceptions with which the soft-tissue envelope is directly affected by a malformation (e.g., Treacher Collins syndrome, hemifacial microsomia, cleft lip, hemifacial hypertrophy), previous trauma (e.g., burns, lacerations), or scarring after infection. When a jaw deformity is associated with a syndrome (see Chapters 27 through 31), clefting (see Chapters 32, 33, and 34), or a soft-tissue traumatic deformity (see Chapter 35), the soft-tissue envelope may require special consideration.

Evaluation of the Upper Facial Skeleton

For most individuals who present with dentofacial deformities, the upper facial skeleton (i.e. cranial vault, orbits, and zygomas) will be reasonably symmetric and proportionate. There are exceptions that result from 1) congenital anomalies (e.g., craniofacial microsomia, Treacher Collins syndrome, Apert syndrome, Crouzon syndrome), 2) traumatic events (e.g., molding during infancy, torticollis, previous facial bone fractures with malunion), and 3) tumors (e.g., fibrous dysplasia, neurofibromatosis).

With routine dentofacial deformities, minor upper face skeletal variations from normal are expected; they may include differences in the convexity of the forehead (i.e., the anterior cranial vault) or the prominence of the supraorbital ridge (i.e., anterior frontal sinus wall bulging). Minor mirror-image asymmetries of the upper face are also common (e.g., external ear position, eyebrow height, cranial nerve VII dysfunction). When present, facial variations and asymmetries should be documented through medical-quality photographs and then discussed with the patient and his or her family from the outset.

In the presence of a dentofacial deformity the cheeks and cheekbones may appear bigger or smaller than they actually are. The correction of the jaw deformity toward Euclidian proportions is likely to change the observer's impression. An example of this phenomenon is seen in the patient with maxillary deficiency in combination with relative mandibular excess (Fig. 12-35, *K* & *L*). When the maxilla is advanced and rotated clockwise in conjunction with mandibular ramus osteotomies, the apparent flat cheekbones, deficient infraorbital rims, and enlarged nose typically disappear (see Chapter 20).

Evaluation of Unique (Discrete) Facial Aesthetic Units

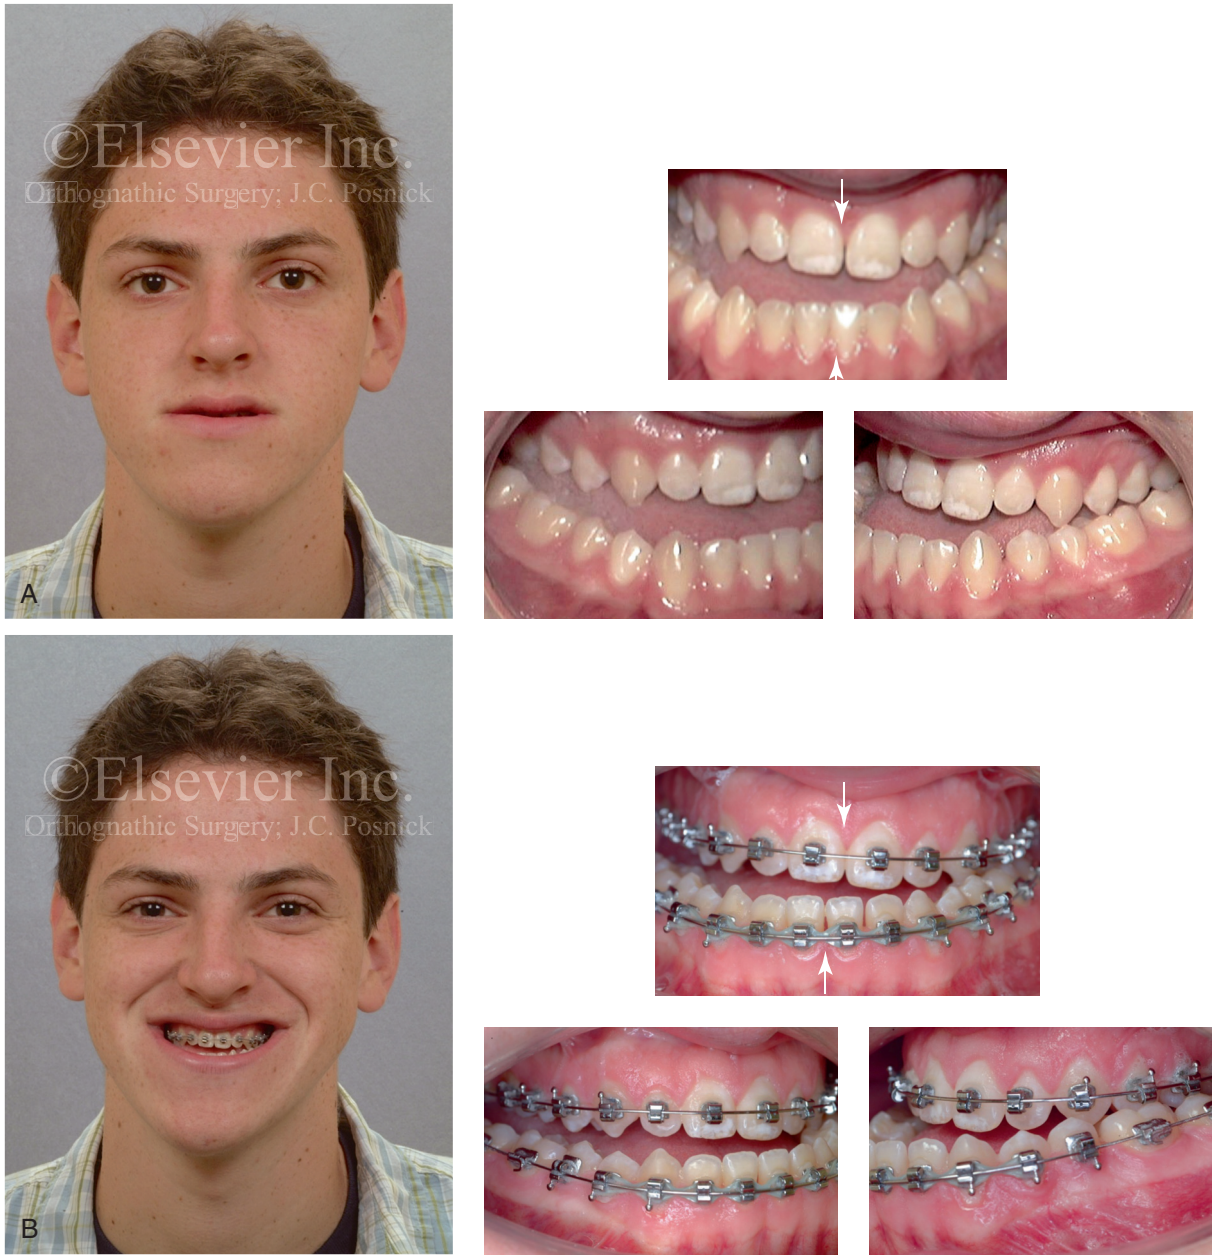
There are discrete aesthetic units of the face that stand out and that should be independently considered, including the periorbital (eyelid) regions, the external ears, and the nose.

The *periorbital (adnexal) tissues* may be of special concern as a result of 1) congenital hypoplasia (e.g., Treacher Collins syndrome, hemifacial microsomia, upper eyelid ptosis), 2) previous trauma (e.g., medial or lateral canthal injury, nasolacrimal apparatus injury, upper or lower eyelid injury), or 3) the normal aging process (e.g., descent, deflation, ptosis). The individual's eyelid appearance may either add a sparkle to or be a distracting focal point of the face. For example, distortions of the lower eyelids are generally seen in patients with dentofacial deformities that are associated with maxillary deficiency and relative mandibular excess (i.e., negative vector relationship of the eyeballs and lower lids). This negative vector relationship affects the aesthetic appearance of the midface, which only worsens with age (see Chapter 25 and Fig. 12-35, *D*). Maxillary horizontal advancement and clockwise rotation in conjunction with mandibular ramus osteotomies corrects the skeleton and has positive effects on the soft tissues of the eyelids and the midface contours (see Chapter 20 and Fig. 12-35, *K* & *L*).

The *external ears* display considerable variations in size, shape, extent of protuberance, and asymmetry (see Chapter 39). Forensic pathologists consider details of auricular morphology to be as unique to the individual as that individual's fingerprints. In association with specific syndromes (e.g., hemifacial microsomia, Treacher Collins syndrome), there may be auricular hypoplasia or a malformation that ranges from total microtia to cupping to just an abnormal location of the ears on the side of the face (see Chapters 27 and 28). Significant disproportion of the external ears, as a standalone and distinct feature, can be a distracting aesthetic aspect in the presence of an otherwise attractive face. An external ear set-back procedure may be carried out as part of the orthognathic surgery or later as a separate operation (see Chapter 39).

The *external nose* will display a wide range of aesthetic variation due to unique bony, cartilaginous, and soft-tissue anatomy (see Chapter 38). In the presence of a dentofacial deformity, the middle third of the central face (i.e., the nose) may appear bigger or smaller than its actual size (Fig. 12-35, *L*). The correction of the presenting jaw discrepancy toward Euclidean proportions will improve harmony between the upper, middle, and lower thirds of the face. After this is accomplished, a more accurate assessment of the actual nasal aesthetic unit can be made. Disproportion of the nose as a standalone aesthetic unit may nevertheless exist and benefit from alteration (see Chapter 38). Dysfunction of the nose characterized by chronic obstructive nasal breathing and inadequate sinus drainage should also be recognized and dealt with at the appropriate time (see Chapter 10). Clarification of these issues with the patient and his or her family at the first consultation visit as well as additional discussion at the time of orthognathic planning and again after surgical healing is essential to achieve patient satisfaction (see Chapter 7).

Text continued on p. 360



• **Figure 12-35** A 17-year-old boy with a diagnosis of left hemimandibular elongation. This dentofacial deformity affects the patient's chewing, swallowing, speech articulation, lip closure/position, and breathing. He has normal cervical spine function and neck range of motion. He has no temporomandibular disorder, and he has a full range of mandibular motion. The upper facial skeleton (i.e., the cranial vault, the orbits, and the zygoma) is symmetric and with normal proportions. The facial soft-tissue envelope is distorted by the maxillomandibular deformity but without malformation. During his early teenage years, the patient underwent an initial phase of orthodontics without success. He was referred for surgical evaluation and then underwent a combined orthodontic and surgical approach. With the relief of dental compensation, his surgery included a maxillary Le Fort I osteotomy in segments (horizontal advancement, cant correction, vertical change, arch expansion, and clockwise rotation); bilateral sagittal split ramus osteotomies (cant correction and mandibular straightening); osseous genioplasty (straightening and minimal advancement); and septoplasty/inferior turbinate reduction. **A,** Frontal facial view in repose before treatment. Occlusal views before orthodontic retreatment are also shown. **B,** Frontal view with smile before surgery. Occlusal views with orthodontic (dental) decompensation in progress.

Assessment for Temporomandibular Disorder and Current Mandibular Range of Motion

An accurate history of any past and current temporomandibular disorder symptoms and signs should be documented, including any previous therapy; subjective complaints; joint noise; mandibular range of motion; any centric relation–centric occlusion discrepancy; masticatory muscle tenderness to palpation; and current radiographic findings. Any active temporomandibular disorder will require treatment to diminish symptoms and to achieve adequate range of motion before orthodontic treatment is initiated (see Chapter 9).

Assessment of the Cervical Spine and Current Neck Range of Motion

An accurate history of past and current cervical spine symptoms and signs should be documented. Individuals with a dentofacial deformity are at higher-than-average risk for cervical spine anomalies. If the suspicion of cervical spine dysfunction exists, consultation with an appropriate specialist (i.e., neurologist, orthopedic surgeon, neurosurgeon) and the obtaining of focused imaging studies (i.e., magnetic resonance imaging, computed tomography scanning, plain radiographs) should be carried out. Confirming the safe range of motion of the neck with the patient awake in the office setting and understanding any limitations is important for safe orthognathic surgery and recovery.

Evaluation of the Lower Facial Skeleton

Confirmation that the upper facial skeleton and the soft-tissue envelope of the face do not require surgical alteration and that the neck and mandible have an intact safe range of motion without significant limitations or discomforts is essential before focusing on detailed maxillomandibular surgical planning.[142]

Qualitative decisions concerning which components of the maxillomandibular skeleton are asymmetric or disproportionate and thus require surgical repositioning will have already been discussed with the patient, his or her family, and other treating clinicians before the initiation of treatment. These details should be reconfirmed by the orthognathic surgeon during the immediate preoperative planning visit.[120,121,130,131,132,152,153,155,170]

Assuming that both the maxilla and the mandible are part of the dentofacial deformity that requires reconstruction, quantitative (to the millimeter) decisions of the preferred aesthetic and best functional repositioning of the upper jaw (at the time of the Le Fort I osteotomy) must first be made.* When thinking through the details of maxillary surgical repositioning, it is understood that the "new" upper jaw position (in two-jaw surgery) will serve as the platform on which the mandible is to be placed. Where the lower jaw ends up is important and will be entirely dependent on the new surgical position of the maxilla and the orthodontic alignment of the teeth.[159,160,187,195,196,198,205,212,213,214,216-221,235-237,240]

Evaluation of Overall Dental Rehabilitation Needs

Recognizing when a patient who is seeking orthognathic surgery has additional dental needs beyond standard orthodontics is essential to the achievement of a favorable outcome. The need for *periodontal evaluation and treatment* as well as the need for *complex dental restorative work* should be considered for every patient before the initiation of a coordinated orthodontic and jaw surgical approach. This is especially true for the individual who has suffered dental and periodontal sequelae from a longstanding uncorrected dentofacial deformity and who may have undergone camouflage treatment in an attempt to neutralize the occlusion (e.g., orthodontics, occlusal equilibration, restorative dentistry) (see Chapters 5 & 6).

Detailed Maxillomandibular Surgical Planning: Eight Critical, Quantitative, To-the-Millimeter Decisions

1. Assess the current and preferred position of the *maxillary dental midline* with reference to the upper face (i.e., yaw orientation). Anticipate any potential yaw effect of the new surgical maxillary orientation on the mandible and the midface (i.e., the cheeks) (see Fig. 12-35, *B*).
2. Assess for the presence of any *maxillary cant* (i.e., roll orientation) with reference to the upper face. Determine the preferred upper jaw repositioning for cant correction (see Fig 12-35, *B*).
3. Assess the current and preferred *vertical position of the maxillary incisor crown* with reference to the upper face. Consider the upper-lip–incisor relationship in both repose and smile (see Fig 12-35, *A* and *B*).
4. Assess the current and preferred *horizontal position of the maxillary incisor crown* with reference to the upper face (see Fig 12-35, *D*).
5. Assess the current and preferred *A-point to B-point relationship of the jaws* (i.e., pitch orientation). When the face is viewed in profile in the NHP, consider the need to differentially alter the vertical maxillary height at the first molars and the incisors (i.e., maxillary plane change) to achieve specific objectives (see Fig 12-35, *D, E,* and *F*).
6. Assess the *baseline pyriform rim, floor of nose, and anterior nasal spine morphology.* Anticipate the location of each after midface reorientation, including any planned maxillary plane change. Consider the advantages of the recontouring of the pyriform rims, the floor of the nose,

*106, 109, 110, 113, 117, 119, 137, 140, 141, 156, 157, 163-165, 167-169, 170, 175, 176, 179, 182, 183, 188, 194, 224, 230-233, 242, 244, 245

and the anterior nasal spine to achieve airway and aesthetic objectives (see Fig 12-35, *D, E,* and *F*).

7. Assess the *baseline chin morphology.* Anticipate the location of the pogonion after jaw reorientation that may also include mandibular plane change (i.e. pitch orientation). Consider the advantages of chin reshaping (i.e., osseous genioplasty) to achieve the preferred horizontal and vertical aesthetics and shape of the chin (see Fig 12-35, *D, E,* and *F*).
8. Reconfirm the advantage of and *need for the segmentation of the maxilla* to achieve the preferred arch form and occlusion with the mandible (see Fig 12-35, *G*).

Assess the Current and Preferred Position of the Maxillary Dental Midline (i.e., Yaw Orientation) with Reference to the Upper Face

After the decision has been made to surgically reposition the maxilla and the mandible (i.e., two-jaw surgery), no additional risk is encountered by making a change in the *maxillary dental midline position*. In fact, the surgeon must make a conscious decision to either leave the midline as it is or to adjust it. During the immediate preoperative, direct, face-to-face examination, the operating surgeon should consider the preferred location of the maxillary dental midline.[10,117,120,167,176,183] This is a clinical observation when viewing the patient at conversational distance and closer up. It is measured in millimeters of variation of the current maxillary dental midline position (i.e., the point between the incisors at the incisal edge) in comparison with the baseline upper facial midline.

Ideally, the midline between the maxillary central incisors should coincide, within 2 mm, with the facial midline. When the upper face has satisfactory basic symmetry, the decision of where to position the maxillary dental midline is generally straightforward (see Fig. 12-35, *C*). In the presence of upper face asymmetry—especially in combination with canting of the maxilla and asymmetry or disproportion of the mandible (see Chapter 28)—the decision of where to reposition the maxillary midline becomes more complex.

When the surgeon determines the preferred (new) location of the maxillary dental midline, the *yaw effect of the midline change* must also be taken into account (see Fig. 12-35, *G*). For example, the maxilla may be either bodily moved to one side to correct the incisor midline, or the maxillary dental midline maybe corrected while leaving the buttress regions (i.e., side to side) essentially unchanged. This would require a *twisting* of the maxilla rather than a *bodily* movement so that the posterior maxilla moves slightly anterior on one side while the other side moves slightly posterior. This is a similar movement to the twisting open of a lid on a jar. As stated, a twisting movement of the maxilla around the vertical axis of rotation (i.e., yaw orientation) results in an incisor midline shift and a simultaneous anterior-posterior shift at the molars. When twisting the maxilla, the resulting posterior shift will cause a relative Class III on one side and a Class II molar relationship on the other side. Alternatively, a lateral (side-to-side) shift of the maxilla would cause a different change in the yaw orientation (see Fig. 12-35, *H*).

Establishing the correct maxillary dental midline position and yaw orientation is especially of concern in cases that present with moderate to severe three-dimensional facial asymmetry of multiple bones (i.e., hemifacial microsomia). A three-dimensional computed tomography scan (i.e., from the top of the skull through bottom of the chin) can be helpful to appreciate where specific mirror-image dysmorphology exists and how best to manage it (see Chapter 27 & 28).

During orthognathic surgery, the introduction of yaw effects may later be visualized as unwanted facial asymmetry in the following areas:

- The *maxillary incisor midline* as compared with the upper facial midline
- The *cheek region,* with fullness on one side and deficiency on the other
- The *angle of the mandible region,* with fullness on one side and deficiency on the other

Assess for the Presence of Any Maxillary Cant (i.e., Roll Orientation) with Reference to the Upper Face

When the decision has been made to surgically reposition both the maxilla and the mandible (i.e., two-jaw surgery), no additional risk is encountered when correcting any observed *cant (i.e., roll orientation)* of the maxilla. The operating surgeon is forced to make a conscious decision to either leave the roll orientation (cant) as is or to alter it and, if so, by how much. Studies confirm that a 3-degree occlusal cant is perceived as a noticeable asymmetry by 50% of both professionals and lay people, whereas a 4-degree cant is noticeable by 90% of professionals and lay people.

During the preoperative direct planning examination, the clinician should make an observation when viewing the patient face to face of whether the maxilla is vertically even (i.e., from side to side) or, if not, of how much of a deviation (cant) is present.[109,117,141,157,192,231] What is generally considered a maxillary cant (i.e., vertical height discrepancies of the maxilla from side to side) may also be viewed from the perspective of the *aesthetic line of the dentition* or at the *functional line of the occlusion* (see Fig. 12-35, *J*). Maxillary cant considerations take into account the upper face (i.e., the structures above the maxilla). When the upper face is basically symmetric, the interpupillary line may be used as an accurate baseline reference (see Fig. 12-35, *B* and *C*).

The presurgical planning visit is a good opportunity for the surgeon to clarify and discuss directly with the patient and his or her family both major and minor presenting facial asymmetries. This can be done by viewing a medical-quality frontal facial photograph or while the patient is viewing himself or herself with a handheld mirror. Typical

minor asymmetries include differences in the height (position) and shape of the external ears, the eyebrows, and the lateral canthi as well as asymmetries in cheek and lip (i.e., soft-tissues) elevation during smiling.

The quantifying of any presenting maxillary cant and the extent of correction planned (to the millimeter) may be complicated by upper facial skeletal asymmetries; other directional abnormalities of the maxilla (e.g., transverse, horizontal, or dental midline to facial midline); and any asymmetry or disproportion of the mandible. When present, these compounding factors make it difficult to accurately predict the most aesthetically pleasing outcome.

Thought is simultaneously given to the *yaw orientation* (i.e., rotation around the Y axis) of the presenting maxillary deformity and the yaw effect at the level of the mandibular angles and the midface (cheek) regions anticipated as a result of the (planned) maxillary change (see Fig. 12-35, *G*). In complex facial asymmetry cases, the clinician's ability to simultaneously analyze the presenting yaw and roll orientations and the subsequent aesthetic changes of the planned correction can be augmented with the use of craniofacial three-dimensional computed tomography scan imaging.

The clinicians' assessment of the extent of maxillary cant and the desired correction may be facilitated by the following:

1. Use of a *Fox plane* during the direct visual examination. The placement of a Fox plane directly over the occlusal surfaces of the maxillary dentition is helpful to judge the presence and extent of maxillary cant as compared with the upper face (i.e., the interpupillary reference line). Soft wax can be added to the deficient side (i.e., wax can be placed in between the Fox plane and the occlusal surfaces of teeth) until the cant is corrected. The millimeter amount of wax buildup (e.g., at the first molar) is a measure of the cant. When using a Fox plane, the clinician must also consider the patient's maxillary arch form. Often, two separate dentoalveolar planes (i.e., in the presence of a steep curve of Spee) have been accentuated by the orthodontic mechanics and will be managed with segmental osteotomies. How the Fox plane is seated to the patient's maxillary occlusal plane is important when assessing for a cant.
2. Comparison measurements from a *posterior-anterior cephalometric radiograph* (left side to right side)
   - Incisal edge to nasofrontal suture (millimeter distance, left and right sides)
   - Canine edge to nasofrontal suture (millimeter distance, left and right sides)
   - First molar edge to frontozygomatic suture (millimeter distance, left and right sides)
3. Comparison measurements from a *three-dimensional craniofacial computed tomography scan* (left side to right side)
   - Incisal edge to nasofrontal suture (millimeter distance, left and right sides)
   - Canine edge to nasofrontal suture (millimeter distance, left and right sides)
   - First molar edge to frontozygomatic suture (millimeter distance, left side and right side)
4. Comparison measurements taken directly from the *anthropometric (facial) surface* (left side to right side)
   - Incisal edge to medial canthus (millimeter distance, left and right sides)
   - Canine edge to medial canthus (millimeter distance, left and right sides)
   - First molar edge to lateral canthus (millimeter distance, left and right sides)

Assess the Current and Preferred Vertical Position of the Maxillary Incisor Crown with Reference to the Upper Face

The relationship between the upper lip and the maxillary incisors represents a key facial aesthetic landmark. Ideally, with the upper lip at rest, several millimeters (i.e., 1 mm to 3 mm) of the lower aspect to the maxillary incisor crowns should be seen in frontal view. With a broad smile, the upper lip elevates and, ideally, the entire maxillary incisor crown and at least a few millimeters of the gingiva will be seen. This will vary when evaluating a *posed smile* (as for a photograph) versus a *dynamic smile* (as seen when laughing).* The *aesthetic line of the dentition* follows the surfaces of the maxillary anterior and posterior teeth. The *functional line of occlusion* takes into account arch form, arch width, and symmetry. In the presence of malocclusion—as a result of distortions in arch width, curve of Spee, and overall arch form—the functional line of occlusion may not be even or on a single plane (see Fig 12-35, *J*). With many of the typical developmental jaw deformities, the *lip-to-tooth relationship* (i.e., the aesthetic line and the functional line) will show variation from ideal. Affected individuals will benefit from differential surgical repositioning of the anterior and posterior maxilla (i.e., intrusion or lengthening) as part of the surgical correction not only to positively influence the occlusion itself but also to influence the aesthetic line of the dentition and the functional line of occlusion.

Through a Le Fort I osteotomy with vertical intrusion, less gingiva with smile and incisor crown height in repose will be seen. With surgical (vertical) lengthening of the upper jaw during the Le Fort I osteotomy, more dental show and gingival exposure are to be expected (see Fig 12-35, *I* and *J*). Unfortunately, even with a pure vertical vector change of the maxilla, the upper lip soft-tissue response is generally less than a one-to-one relationship and not entirely predictable. Soft-tissue predictions become even less accurate in combination with other upper jaw vector changes (i.e., horizontal, and transverse); in the presence of maxillary asymmetries (i.e., cant and dental midline shifts); when other procedures are simultaneously carried out (e.g., mandible and chin osteotomies, pyriform rim/nasal floor/

*References 106, 110, 130, 131, 137, 140, 152, 173, 179, 194, 209, 218, 220, 230, 233, 244, 250

anterior nasal spine recontouring); and in the presence of a hypotonic upper lip (e.g., longstanding skeletal Class III malocclusion) or an immobile scarred upper lip (e.g., fibrosis after cleft lip repair).

Nevertheless, with thoughtful planning, a favorable aesthetic outcome involving the relationship of the *incisor vertical position to the upper lip* should be achieved for the vast majority of orthognathic patients (see Fig. 12-35, *I* and *J*). As a general rule, it is best to prevent too little maxillary incisor and gingival show in relationship to the upper lip, because this will result in an edentulous, aged, or sad look. Remember that, with age, the upper lip lengthens as a result of a loss of muscle tone. As long as excess lip separation at rest and mentalis strain with closure are avoided, erring on the side of more rather than less incisor show is generally the preferred aesthetic objective.

NOTE: I prefer to make final decisions regarding the exact aesthetic vertical position of the maxillary incisors during operation after the maxilla is secured to the mandible through the intermediate splint. At this point, with the condyles seated in the terminal hinge position, all other vector changes for the maxilla are predetermined. The maxillomandibular complex is rotated, the vertical height is measured (i.e., medial canthus to incisor height), and the final vertical incisor position is determined.

Assess the Current and Preferred Horizontal Position of the Maxillary Incisor Crown with Reference to the Upper Face

The "ideal" aesthetic horizontal (sagittal) position of the maxilla is not an exact millimeter number but rather a narrow range of what will be considered proportionate within the overall face. For each specific developmental jaw growth pattern (e.g., long face or short face growth pattern, maxillary deficiency with relative mandibular excess, cleft maxilla), the needed directional horizontal surgical change of the maxilla should be clear at the initial consultation. This will be reconfirmed during the preoperative planning examination by the operating surgeon. The preferred *horizontal (millimeter) change at the maxillary incisors* can be gauged through a combination of analyses:

1. *Cephalometric analysis.* A lateral cephalogram of the patient is taken in (or adjusted to) the NHP, in centric relation, and with the lips relaxed.
2. *Andrews' analysis.* A lateral facial photograph of the patient is taken in (or adjusted to) the NHP, in centric relation, with a broad smile (i.e., exposing the maxillary incisors) and with the exposure of the forehead skin (i.e., with the hair pulled back).
3. *Anthropometric surface analysis.* A direct visual examination of the patient's face is made by viewing him or her in the NHP from various perspectives, both in repose and with a smile.

COMMENT: Normative cephalometric measurements (e.g., the sella-nasion-A point angle) generally underestimate but may also overestimate the preferred horizontal aesthetic projection of the maxilla and therefore cannot be relied on. Alternatively, an Andrews' analysis of how much to advance the maxilla in the sagittal plane can be a useful aide to the clinician when evaluating a patient with a dentofacial deformity. Spending time with an experienced orthognathic surgeon is a valuable way for a clinician in training to gain the hands-on knowledge required to make consistent favorable aesthetic judgments of the preferred three-dimensional reorientation of the maxilla during the operation.

As stated, *Andrews' analysis* can be a helpful tool to assess the preferred horizontal (sagittal) projection of the maxilla in the patient with a dentofacial deformity. This author's application of Andrews' "Element II of Orofacial Harmony" is illustrated in Figure 12-36. A step-by-step outline of how to do so is also given here:

- View a photograph of the individual's head and neck in profile. The photograph is best taken in the NHP and with a broad smile so that the labial surfaces of the maxillary incisors are fully visualized. The forehead skin up to the hairline must also be exposed, so the hair should be pulled back, if necessary. There should be a calibration scale on the facial photograph to confirm that it is life size (i.e., 1 to 1) so that accurate measurements can be made.
- Identify the *trichion:* This is the junction of the forehead skin and the anterior hairline. It is considered the most superior aspect of the forehead when the forehead contour is relatively flat.
- Identify the *superion:* This is typically considered the most superior aspect of the clinical forehead. This is the point used when the forehead is either rounded or angular in contour.
- Identify the *glabella:* This is the most anterior projection of the lower forehead.
- Draw a line that connects the superion and the glabella (assuming that the patient has an angular or rounded forehead).
- Identify the midpoint between the superion and the glabella: This is called the *forehead anterior point* (FA point).
- Locate and drop a vertical line through the FA point. This line should be perpendicular to the floor when viewing the patient's photograph in the NHP. This is called the *forehead anterior limit line* (FALL).
- Measure the angle at the superior forehead between these two lines. This angle is a measure of *forehead inclination*.

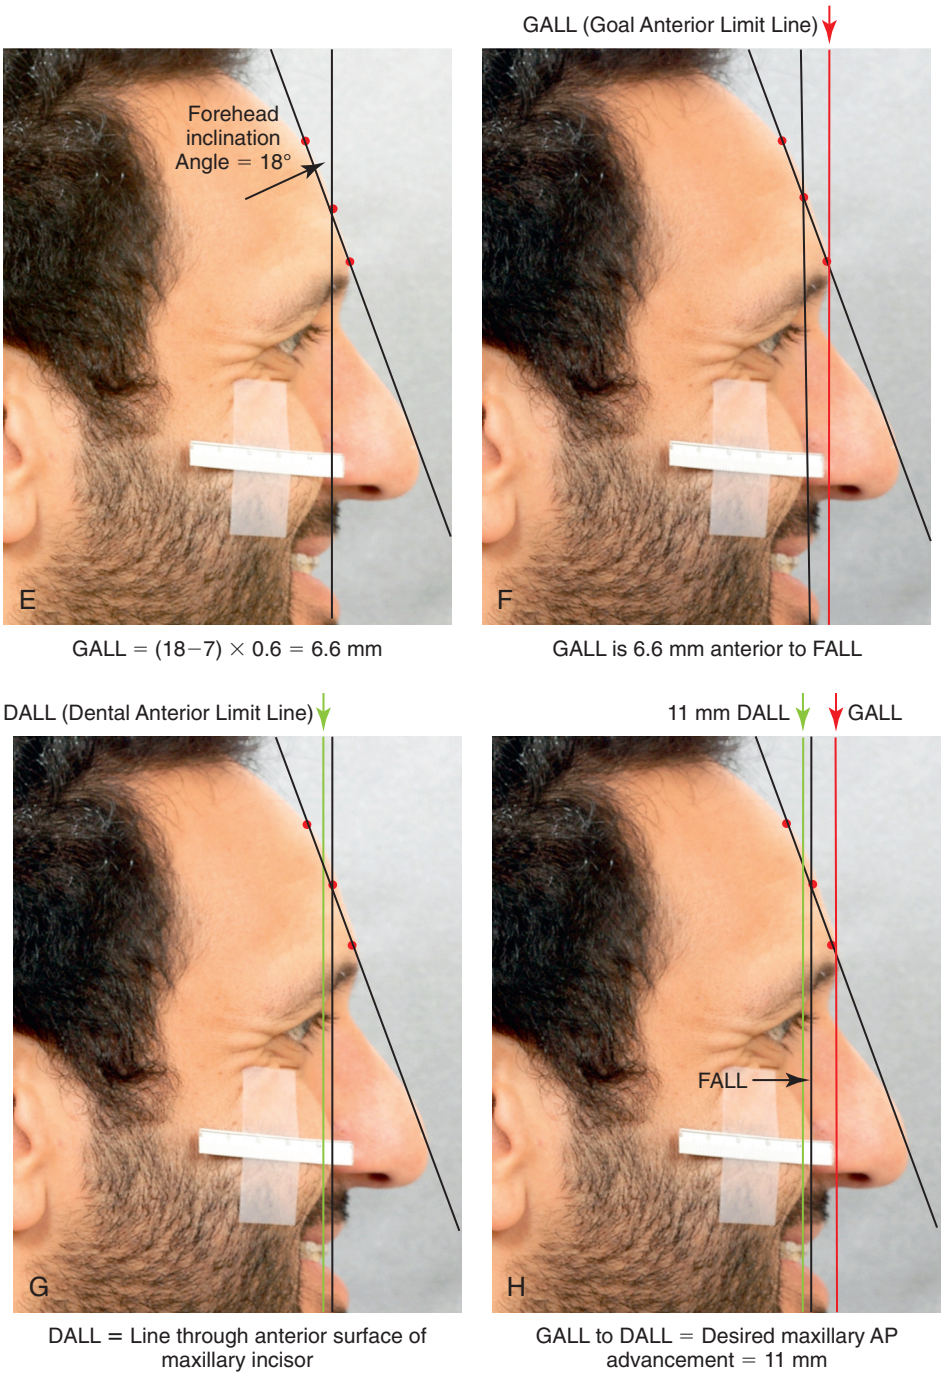
• **Figure 12-36** Patient viewed in profile in the natural head position (NHP). He is shown as a case example to demonstrate application of Andrews' "Element II of Orofacial Harmony." (See text for explanation.)



• **Figure 12-36, cont'd**

- Locate and drop a second vertical line that is anterior and parallel to the FALL. This second line is called the *goal anterior limit line* (GALL). The location of this line is measured in millimeters anterior to the FALL in accordance with the following standard formula: (Forehead inclination angle − 7) × 0.6 = _____ mm.
- Locate and drop a third vertical line that is parallel to both the FALL and the GALL. This line is called the *dental anterior limit line* (DALL). The line runs through the anterior surface of the maxillary incisors. The difference (in mm) between the GALL and the DALL is the "recommending" distance that the maxilla should be horizontally (sagittally) advanced to improve midface aesthetics in the patient with a maxillary deficiency. This is assuming that Andrews' Element I is correct (i.e., that

NOTE: If the GALL is anterior to the glabella, then locate and drop a fourth vertical line (through the glabella) that is parallel to the others. This represents the maximum horizontal position for the incisor to achieve preferred midface aesthetics (i.e., rather than the GALL).

the proper arch shape-positioning of the maxillary teeth [roots] over basal bone is correct).

Additional Considerations to Andrews' Standard Analysis

- I have found that Andrews' analysis for the preferred maxillary incisor position (i.e., Element II) is best suited for Caucasian patients. When applying Andrews' formula to Asian, African, or Indian morphology, caution is warranted. Facial variations in forehead, nasal, and midface morphology are characteristically influenced by *race*.
- I have found that variations in *skin thickness* can have a significant effect on the preferred aesthetic sagittal position of the maxilla. This is an additional factor that should be taken into account when reorienting the maxilla in conjunction with a Le Fort I osteotomy. For example, the individual with a thick soft-tissue envelope (e.g., a patient with obstructive sleep apnea and an elevated body mass index) may handle a greater horizontal advancement than Andrews' analysis indicates. The opposite may be true for the individual with a thin soft-tissue envelope.
- Andrews points out that midface aesthetics in profile are highly dependent on the *ideal positioning of the maxillary teeth* within the arch (i.e., Element I). An example of this is seen in the patient with a maxillary deficient and relative mandibular excess growth pattern. If maxillary bicuspid extractions are not carried out (when required) to provide space for the orthodontic retraction of the incisors toward a normal inclination, then midface aesthetics will be negatively affected. Unless *Element I* has first been achieved, the procumbent maxillary incisors will negatively affect the nasolabial angle in repose, the draping of the upper lip with a smile, and the baseline nasal base aesthetics.

The achievement of *a favorable smile* is influenced by several factors, including but not limited to: 1) the quality of the perioral soft tissues 2) the vertical position of the maxilla 3) the horizontal position of the maxilla 4) the maxillary arch width and 5) the inclination of the anterior teeth within the arch (see Fig. 35, *I* and *J*). The *smile arc* is analyzed in the frontal view by evaluating parallel lines that represent the lower lip and the upper dentition. The ideal smile arc (i.e., the consonant smile line) is characterized by the curvature of the lower lip line parallel to the curvature of the maxillary incisal edges. A *consonant smile line* is felt to project a happy and youthful appearance. The *buccal corridor* is the space that is created between the buccal surfaces of the posterior teeth and the inner aspect of the oral commissure when the individual is smiling. Those with excessive buccal corridors (i.e., negative space) are generally rated as having less attractive smiles than those with smaller buccal corridors. When the maxilla is narrow and horizontally retrusive, the visual appearance of dark buccal corridors reduces the attractiveness of the smile. Smile aesthetics are enhanced when the *display zone* is filled with the maxillary teeth. This concept is best appreciated when viewing photographs of the smile before and after orthognathic surgery for an individual with maxillary deficiency in combination with relative mandibular excess who presents with a Class III negative overjet malocclusion (see Fig. 12-35, *I* and *J*). The improvement of the *smile aesthetics* in the patient with a maxillary deficiency are often accomplished through a combination of maxillary arch expansion, horizontal advancement, and the adjustment of the vertical height.

NOTE: Decisions regarding where to position the maxillary incisor vertically and horizontally at the time of Le Fort I osteotomy will greatly affect smile aesthetics.

When determining the preferred horizontal (surgical) repositioning of the maxilla, an important facial aesthetic consideration is the interrelationship of the anterior maxillary wall (i.e., above the alveolar process), the ocular globes, and the lower eyelids (see Fig. 12-35, *D*). Horizontal advancement and clockwise rotation of the upper jaw (after Le Fort I osteotomy) for individuals who present with maxillary deficiency and relative mandibular excess are typically required to achieve and maintain favorable periorbital aesthetics (i.e., *a positive vector relationship;* see Chapter 20).

William Hogarth was an artist during the mid 1700s who published an analysis of facial beauty.[188] He documented the aesthetic importance of establishing an unbroken convex contour from the lower eyelid to the cheek (see Fig 12-35, *L*). He felt strongly that this convex shape, also called the *midface ogee curve,* was fundamental to a youthful and attractive midface. Dr. John Little further characterized the ideal midface ogee curve when viewing the individual at conversational distance.[170] This can also be appreciated on a medical-quality, high-resolution, oblique facial photograph. Little suggested that the surgeon use the midface ogee curve as an aesthetic reference standard when attempting to rejuvenate an aging face.

A lack of this youthful cheek region is often seen in individuals with either a long face Class II mandibular deficiency anterior open-bite growth pattern (see Chapter 21) or a maxillary deficiency relative mandibular excess growth pattern (see Fig. 12-35, *D*). Projecting the midface forward and appropriately rotating the maxillary plane (i.e., pitch orientation) as part of the orthognathic correction is often useful to recreate the *natural attractive curvatures and*

NOTE: Some cosmetic surgeons attempt to camouflage the individual's maxillary deficiency either with the excess injection of subcutaneous soft-tissue fillers (e.g., fat grafts, collagen) or with the placement of hard implants (e.g., Silastic, porous polyethylene) rather than using an orthognathic approach (see Chapter 40). I believe that a surgical camouflage approach is counterproductive in most cases; it will result in a less favorable facial appearance as compared with a biologic orthognathic approach, and it runs the risk of leaving the patient with an unnatural and "operated" look.

contours of the otherwise deficient midface (see Fig. 12-35, *L*). This generally requires *counterclockwise rotation* for the long face growth pattern and *clockwise rotation* for the maxillary deficient relative mandibular excess growth pattern.

Assess the Current and Preferred A-Point to B-Point Relationship of the Jaws (i.e., Pitch Orientation)

The facial aesthetic advantage of achieving an ideal *A-point to B-point relationship* has been discussed by contemporary orthodontists and orthognathic surgeons.[109,161,162,187,198,205,212-217] The individual who presents with a dentofacial deformity will frequently have a disharmonious A-point to B-point relationship, which results in negative influences on facial aesthetics (see Fig. 12-35, *D*). This deviation from ideal, when viewed in profile and in the NHP, tends to be predictable in accordance with the specific pattern of developmental jaw deformity (e.g., long face growth pattern, maxillary deficiency with relative mandibular excess, primary mandibular deficiency).

For most patients with dentofacial deformities, the achievement of preferred facial aesthetics requires the planned operative rotation of the maxillary and mandibular planes (i.e., *pitch orientation*) to correct A-point to B-point disproportion (see Fig. 12-35, *L* and *N*). This may require *clockwise* or *counterclockwise rotation* of the *maxillary and mandibular planes,* but it rarely requires a true lengthening or shortening of the posterior facial height.[198,205,212-217]

When using sagittal split ramus osteotomies, the unchanged proximal segment of the mandible establishes the posterior facial height, whereas any plane change carried out occurs in the distal segment. *The height of the proximal segment (i.e., the posterior facial height) does not change with either clockwise or counterclockwise rotation of the distal segment in conjunction with a sagittally split ramus osteotomy* (see Chapter 15).

When establishing the preferred A-point to B-point relationship and achieving full midface projection and ideal anterior vertical height through orthognathic techniques, the upper airway will also improve.

The assessment of the profile aesthetics should be made with the patient in the Natural Head Position with the teeth in centric relation and then with the normal freeway space. The lips are first relaxed (i.e., not pursed together) and then also assessed with full smile (see Fig. 12-35 *A, B,* and *D*). Individuals who present with a jaw discrepancy frequently have an altered mode of respiration and tend to rest their heads in positions that an experienced evaluator will view as involving either neck extension or flexion or a head tilt. The adjustment of the individual's head position by the clinician to the NHP is required to accurately assess the profile.

Oftentimes, the patient's lateral facial photograph and lateral cephalometric radiograph are not taken with the patient's head in the NHP. If the profile photograph, the three-dimensional computed tomography scan, and the lateral cephalometric radiograph are to be used for facial aesthetic analysis, then the image should first be rotated to establish NHP (see Fig. 12-35, *D*). From this position, a perpendicular line may be dropped (e.g., from the nasion, the soft-tissue glabella or from subnasion) as a vertical reference line from which to assess the A-point to B-point relationship, the horizontal jaw projection, and the effects on the overlying soft tissues. The clinician should then consider the need for operative rotation (i.e. pitch alteration) of the maxillary and mandibular planes as part of the orthognathic correction. This is to bring the A-point just in front of the B-point and to bring both of them in correct proximity to the vertical reference line (which is perpendicular to the NHP) to achieve enhanced facial projection.

The establishment of a favorable A-point to B-point relationship is an important part of approximating *Euclidian proportions* and of recreating the *natural attractive curvatures and contours of the face* (see Chapter 40). Achieving the preferred A-point and B-point relationship will influence the relative position of the skeletal structures above (i.e., the anterior wall of the maxilla, the pyriform rims, and the anterior nasal spine) and below (i.e., the pogonion) (see Fig. 12-35, *L* and *N*). The position of these superior and inferior skeletal structures will then be reflected through the overlying facial soft-tissue envelope. This includes the soft tissues of 1) the *lower eyelids* (i.e., improvements in the tear trough and the negative vector); 2) the *cheeks* (i.e., improvements in the nasolabial folds); 3) the *nose* (i.e., improvements in depressed nasal sills and a plunging tip); 4) the *lips* (i.e., improvements in turned-down oral commissures and marionette lines); 5) the *chin* (i.e., the prevention of ptosis); and 6) the *neck* (i.e., improvements in an obtuse neck angle and a double chin).

The surgical repositioning of the jaws to improve the A-point to B-point relationship is also carried out with consideration of its effects on the relative inclination of the maxillary and mandibular incisors (see Fig 12-35, *N*). The rotation of the maxillary plane can improve the relationship of the maxillary smile arc to make it consonant with the lower lip. With respect to *incisor inclination,* when the maxillary plane is surgically rotated clockwise, the relative incisor inclination decreases. When the maxillary plane is surgically rotated counterclockwise, the incisors become more procumbent. When the mandibular plane is rotated clockwise, the incisors become more proclined. When the mandibular plane is rotated counterclockwise, the incisors become more retroclined. These effects must be considered during the presurgical orthodontic phase and again at the time of detailed preoperative planning.

Assess the Baseline Pyriform Rims, Floor of Nose, and Anterior Nasal Spine Morphology: Anticipate the Location of each after Maxillary Reorientation

The satisfactory surgical positioning of the A-point and the B-point (i.e., pitch orientation) will generally result in more pleasing aesthetics at the pyriform aperture (paranasal) regions[154,178,198,205,212-217] (see Fig. 12-35, *L* and *N*). However,

at the time of Le Fort I osteotomy, the recontouring of the pyriform rims, the floor of the nose, and the anterior nasal spine region to correct baseline skeletal deformities may also be beneficial (see Chapter 15). The advantage of these recontouring procedures to the upper lip and tooth relationship and the aesthetics of the base of the nose should always be considered during preoperative planning.

Riola's textbook of cephalometric measurements confirms that the normal mean vertical height of the anterior nasal spine down to the maxillary incisal edge is 30 mm (±3 mm) for females and 33 mm (±3 mm) for males.[209] At the time of the Le Fort I osteotomy, the patient's specific measurements can be confirmed with a caliper. This is useful information to guide nasal floor reconstruction. For example, with the long face growth pattern, a patient who is undergoing Le Fort I osteotomy with vertical intrusion to reduce a gummy smile will frequently have an average height of between 38 mm and 45 mm. At the time of LeFort I osteotomy, recontouring and lowering the floor of the nose and the anterior nasal spine toward 30 mm is useful to normalize anatomy. In so doing, the nasal airway and the nasal aesthetic unit will be favorably enhanced (see Fig. 16-19).

Assess the Baseline Chin Morphology: Anticipate the Location of the Pogonion after Jaw Reorientation

An individual's lateral cephalometric radiograph when viewed in the NHP is useful to assess the 1) anterior facial heights, 2) any baseline bony chin dysmorphology, 3) the maxillary and mandibular incisor inclination and 4) the A-point to B-point relationships (see Fig. 12-35, *N*).

Riola's table of normative mandibular cephalometric values confirms that the mean vertical height of the chin (i.e., from the mandibular incisal edge to the menton) is approximately 42 mm (±2.7 mm) for females and 49.4 mm (±2.9 mm) for males.[210] These measurements can be a useful benchmark from which to judge the preferred vertical height of the chin.

The effective alteration of the A-point to B-point relationship at the time of orthognathic surgery will in itself generally have a positive effect on the chins appearance.[198,205,212-217] Additional direct surgical alteration of the chin (i.e., *osseous genioplasty*) is also frequently beneficial to achieve enhanced facial aesthetics (i.e., vertical lengthening or shortening, midline shifts, horizontal advancement or in some cases *recontouring of the chin surface anatomy;* see Chapter 37).

These morphologic details should be considered during the immediate preoperative face-to-face patient examination and discussed with the patient and his or her family. A plan for chin management is agreed to and then executed at the time of orthognathic surgery, with the goals of further improving aesthetics, lip function, and possibly breathing (e.g., genioglossal advancement in the individual with obstructive sleep apnea).

Reconfirm the Advantage of and Need for the Segmentation of the Maxilla

The advantage of segmentation of the maxilla should be considered before the initiation of orthodontic treatment. Maxillary segmentation is often a necessary procedure to achieve favorable long-term occlusal stability and periodontal health. It may also be required to achieve an 1) ideal curve of Spee, 2) arch width, 3) incisor inclination and 4) successful closure of dental gaps.

Segmentation is generally performed as either a *"two-piece"* osteotomy, with an interdental osteotomy between the incisors and then parasagittally through the hard palate, or as a *"three-piece" osteotomy,* with interdental osteotomies between the lateral incisor and canine on each side and then down the parasagittal midline on one or both sides (see Chapter 15).

The segmentation of the upper jaw is not an excuse for poor orthodontic preparation. It does provide an opportunity to correct skeletal issues through the basal bone rather than through orthodontic compensation that would otherwise position the teeth outside or on the edge of the alveolar process (see Chapter 17). An orthodontic compensation (i.e., dental camouflage) approach will likely be unstable for the occlusion and the periodontium in the long run (see Chapters 6 and 17).

These decisions (i.e., plans for maxillary segmentation) should be agreed upon before the initiation of orthodontic treatment, reconfirmed at the time of immediate presurgical model planning, demonstrated on the articulated dental models, registered on the prefabricated acrylic splints, and then executed during surgery (see Fig. 12-35, *G*).

Conclusions

From a patient and family perspective, facial aesthetic aspects are of significant importance to the correction of a dentofacial deformity. The most attractive faces will always incorporate a consistent symmetry of proportions in which the golden ratio can be found.

An in-depth visual facial analysis, the use of radiographic and photographic imaging, meticulous analytic model planning, and experienced surgical execution remain the important components of successful orthognathic surgery. There is much to be said for both the scientific and artistic aspects and a methodical approach to accomplish facial aesthetic objectives, the restoration of dental health, and improved head and neck function (i.e., breathing, swallowing, chewing, and speech) through the reconstruction of a dentofacial deformity. The ultimate objective is the creation of Euclidian facial proportions by attempting to reach the *Kanon* of beauty as described by Polyclitus and as visualized by the nautilus found in nature.

For the correction of a dentofacial deformity, the identification and then the reconstruction of key landmarks of the face are the objectives. In the past, simple but practical tools such as the compass and the square were used to

accomplish these goals. These are similar to the instruments that the 15th-century mathematician Luca Pacioli used to create geometric images and that are used for architecture constructions. The orthognathic surgeon now supplements these tools with computer software programs, three-dimensional imaging, and locating techniques.

In current clinical practice, we can take some solace in knowing that even Leonardo da Vinci was not entirely able to articulate the link between theory and practice for the establishment of ideal facial aesthetics. When analyzing the Mona Lisa, academicians still disagree about Leonardo's intent and the meaning of his work vis-à-vis the golden ratio. Nevertheless, with a working knowledge of the golden ratio and of its fascinating impact on the arts and architecture as well as in nature, the clinician's aesthetic sense of harmony and symmetry is enhanced for the benefit of his or her patients.

Standard Analytic Model Planning for Orthognathic Surgery

JEFFREY C. POSNICK, DMD, MD

- Controversies Surrounding Model Planning for Orthognathic Surgery
- Standard Facial Records for Orthognathic Surgery
- Key Measurements Obtained via Direct Visual Examination to Define Planned Maxillomandibular Surgical Change
- Face-Bow Registration and Transfer to the Semi-Adjustable Articulator
- Use of the Erickson Model Table to Define the Spatial Orientation of an Articulator-Mounted Maxillary Unit
- Use of the Erickson Model Table to Define the Spatial Orientation of an Articulator-Mounted Mandibular Unit
- Separation of the Maxillary Cast from the Articulator Base
- Segmentation of the Maxilla
- Use of the Erickson Model Table Measurements to Reorient the Maxillary Cast
- Intermediate Splint Construction for the Positioning of the Maxilla During Operation
- Reorientation of the Mandibular Cast to Register the Final Occlusion
- Final Splint Construction for the Positioning of the Mandible During Operation
- Finishing of the Prefabricated Acrylic Splints
- Accuracy of the Described Analytic Model Planning Technique: Review of Study
- Conclusions

Unlike most surgical procedures, orthognathic surgery involves not just the thorough medical assessment of the patient but also precise preoperative dental, radiographic, and facial aesthetic planning. The surgeon must carry out a detailed face-to-face examination of the patient to determine variations from normal (Fig. 13-1).

Immediate presurgical records include the following: 1) dental impressions of the maxilla and mandible 2) an accurate bite registration in centric relation (CR) 3) a face-bow recording of maxillary orientation in relationship to the condyles and the upper face and 4) the measurement of specific facial landmarks that includes deviations from normal (Figs. 13-2 and 13-3).

The maxillary model is mounted on a semi-adjustable articulator in accordance with the face-bow recording. The mandibular model is occluded to the mounted maxillary cast with the use of the CR bite[1,2,14,17,18,21,30,52,62,63] (Fig. 13-4). The mounted dental casts are then used to complete model planning[12,50] (Figs. 13-5 through 13-8). Splints made of acrylic are fabricated and used intraoperatively to further ensure the reliable execution of predetermined facial aesthetic and functional objectives (Figs 13-9 through 13-11).

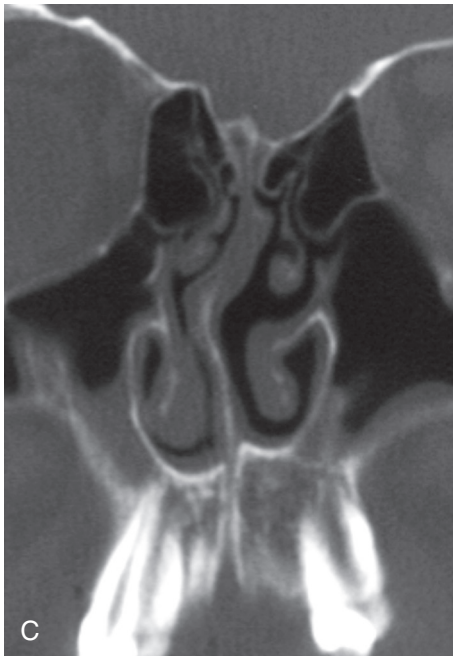
Although clinical decision making regarding the preferred aesthetic reorientation and repositioning of the jaws in the operating room remains both an art and a science (see Chapter 12), the technical aspects of planning should be precise and consistent. Analytic model planning and the use of prefabricated splints continue to represent the standard of care for bimaxillary and segmental maxillary osteotomies.[8,9,15,16,22,26,44,55,77,78,80,85,86]

Despite the benefits of this time-honored approach, there is the potential to introduce error. For example, during bimaxillary surgery, if an inaccurate bite registration is obtained from the patient preoperatively in the clinic setting, this will be transferred to the articulated models; this leads to inaccurate splint construction and then to intraoperative errors when the splints are relied on during surgery. The surgeon's ability to obtain an accurate and reproducible bite registration in CR during the immediate

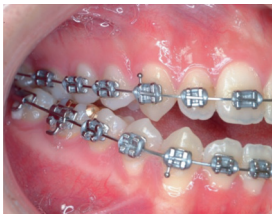
Text continued on p. 405

• **Figure 13-1** A 19-year-old man of Asian descent presented with a maxillary deficient and relative mandibular excess growth pattern. He has an Angle Class III anterior open bite with negative overjet malocclusion as well as a lifelong history of obstructed nasal breathing. The maxillofacial dysmorphology causes difficulties with speech, chewing, swallowing, breathing, and lip closure/posture, and it also negatively affects his facial aesthetics. The upper facial skeleton is symmetric and proportionate; the soft-tissue envelope is distorted but not malformed. There is a good range of motion of the neck and mandible without temporomandibular disorder. After evaluation, a comprehensive orthodontic and surgical approach was discussed and approved. Orthodontic (dental) decompensation required 10 months of active treatment. No extractions were required. Six weeks before surgery, the patient returned for a direct visual examination and the taking of records that included alginate impressions of the maxilla and mandible, centric bite registration, face-bow registration, and the transfer of the data to a semi-adjustable articulator. Decisions were made regarding critical measurements for the surgical repositioning of the jaws. The procedures carried out included the following: a Le Fort I osteotomy in segments (horizontal advancement, cant correction, arch expansion, and clockwise rotation); bilateral sagittal split ramus osteotomies (mandibular adjustment); osseous genioplasty (minimal vertical shortening and horizontal advancement); and septoplasty and inferior turbinate reduction. **A,** Frontal view in repose and occlusal views before treatment. **B,** A Panorex radiograph. This is useful to assess basic condylar morphology and to look for mandibular and dental pathology, including root resorption.

Continued



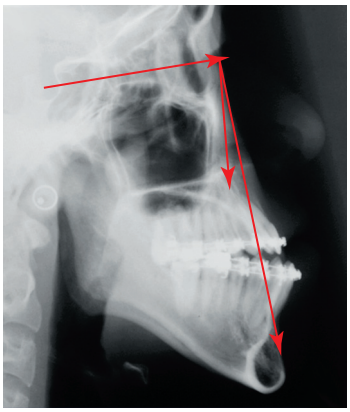
Assess intranasal anatomy
- Septal deviation? "Yes"
- Inferior turbinate hypertrophy? "Yes"
- Tight nasal inlet? "Yes"
- Elevated nasal floor? "No"

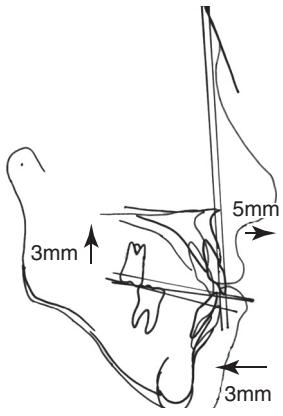


• **Figure 13-1, cont'd C,** The patient's history of lifelong nasal obstruction—in combination with an intranasal speculum and a sinus computed tomography scan examination—confirms a deviated septum (bone and cartilage) and hypertrophic inferior turbinates. Both of these conditions required surgical correction to improve the airway. **D,** Frontal view with smile and occlusal views with orthodontic decompensation in progress.

Maxillary Surgical Plan

Frontal View:	
Maxillary midline	No change needed
Cant correction	2 mm → +1 mm (L), −1 mm (R)
Anterior vertical	No change needed

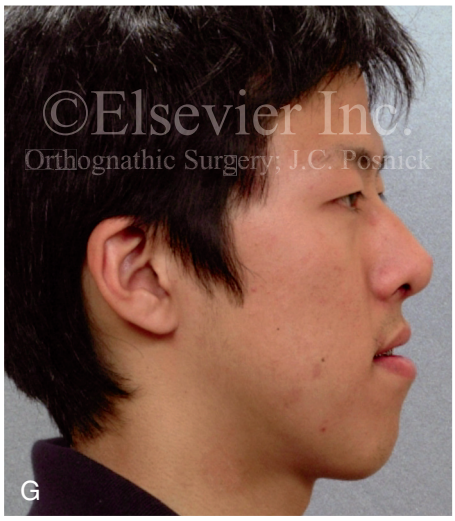




Maxillary clockwise rotation (3 mm) to enhance profile aesthetics

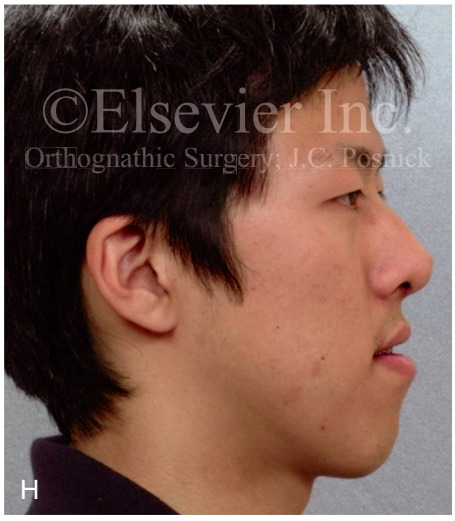
• **Figure 13-1, cont'd** **E,** A frontal facial view confirms that the maxillary midline matches the upper facial midline; that there is a satisfactory lip–tooth relationship in repose and with smile; and that there is canting of the maxilla at the molars (2 mm) as compared with the upper face. **F,** Analysis of the facial profile and the lateral cephalometric radiograph before surgery provides useful information about facial height, incisor inclination, A-point to B-point relationship, maxillary and mandibular projection, and chin morphology.

Continued



Maxillary Surgical Plan	
Profile View:	
Anterior vertical	no change
Posterior vertical	3-mm intrusion
Horizontal	5-mm advance

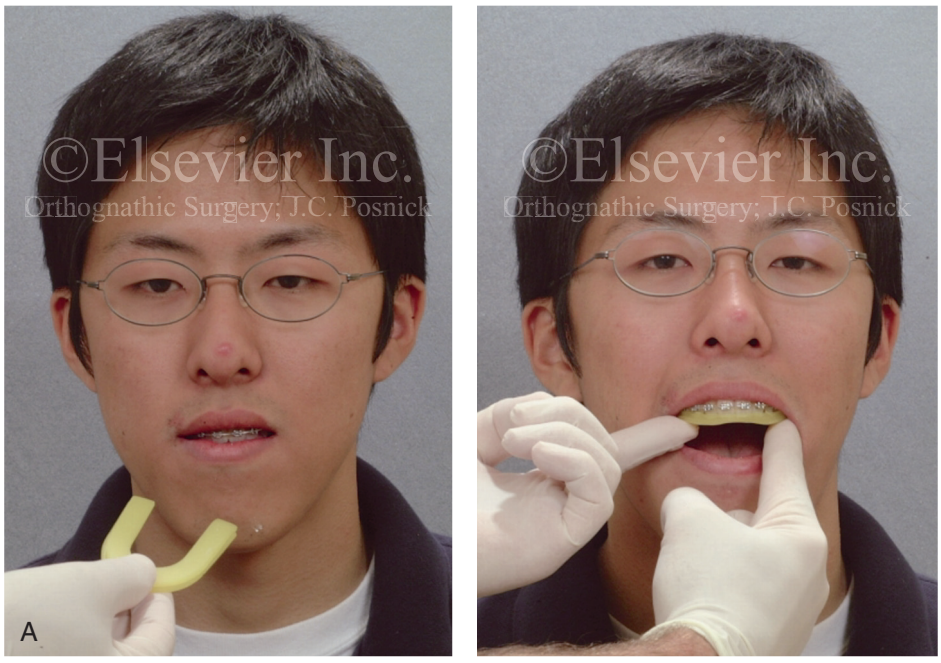
Maxillary clockwise rotation (3 mm) to enhance profile aesthetics



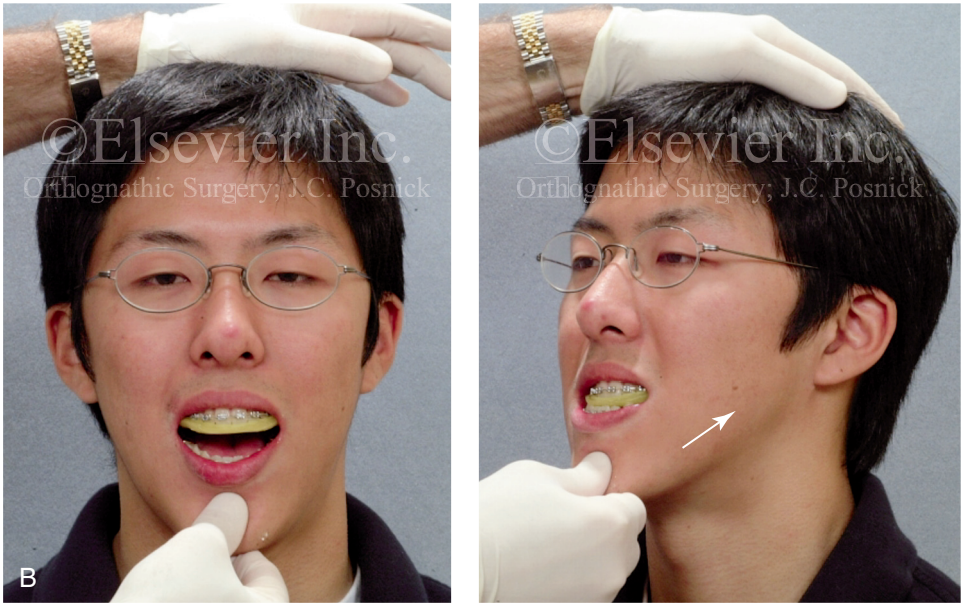
Maxillary Surgical Change	
Horizontal change at incisors	+5
Vertical change at incisors	0
Midline change at incisors	0
Cant correction -*TOTAL*	2
↑−1 on right ↓+1 on left	
Maxillary plane change -*TOTAL* (Clockwise) Counterclockwise	3
Vertical change at T#3 (right) molar (Base + Cant + Plane)	0 −1 −3 = −4
Vertical change at T#14 (left) molar (Base + Cant + Plane)	0 +1 −3 = −2

Measurements are used to spatially reposition the maxilla. The mandible is then set into occlusion with the repositioned maxilla.

• **Figure 13-1, cont'd G,** The direct visual examination of this patient in profile as well as Andrew's analysis confirms the following: an advantage of horizontal advancement at the maxillary incisors (5 mm); no need for vertical change at the maxillary incisors; an advantage of 3-mm clockwise rotation of the maxillary plane (3-mm intrusion at the first molars); and no need for horizontal change at the mandibular incisors. Note that 5-mm horizontal advancement at the incisors will correct the negative overjet and that 3-mm clockwise rotation of the maxillary plane (intrusion at the first molars) will be helpful to restore profile aesthetics and to overcome maxillary incisor procumbancy. **H,** The planned maxillary surgical change is recorded on the orthognathic data sheet. These measurements will be used to spatially reposition and reorient the maxilla first on the articulator for intermediate splint construction and then at the time of Le Fort I osteotomy. During surgery, through sagittal split ramus osteotomies, the mandible will then be set into occlusion with the repositioned maxilla.



"Chin-point guidance" technique for centric relation



"Chin-point guidance" technique for centric relation

• **Figure 13-2** The chin-point guidance technique is used to capture (register) the centric relation bite. The patient is seated upright and in the natural head position. The chin-point guidance technique is accomplished by using one hand to apply pressure to the subject's chin and the other hand to apply counter pressure to their occiput. This allows the clinician to apply posterior and superior "vectored" force on the anterior aspect of the mandible. By doing so, the condyles will be seated in a superior-anterior location within each glenoid fossa (i.e., centric relation). **A,** The registration of the patient's maxillary occlusion into soft wax. **B,** Applying pressure to the chin with the patient's muscles relaxed. The condyles are seated, and the mandible is rotated up until the teeth first occlude. It is essential to avoid a shift (slide) from the centric relation into a centric occlusion. This may occur in a patient with malocclusion if he or she is allowed to fully clench the teeth together.

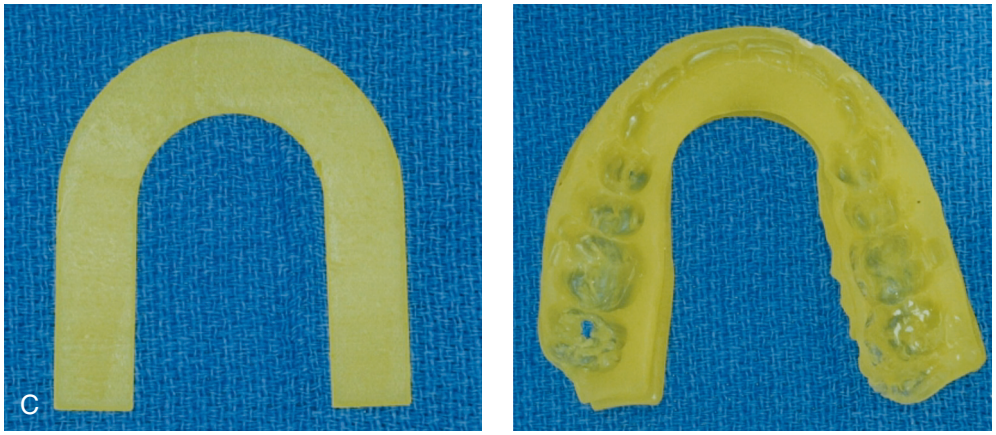
Centric relation (CR) bite (wax)

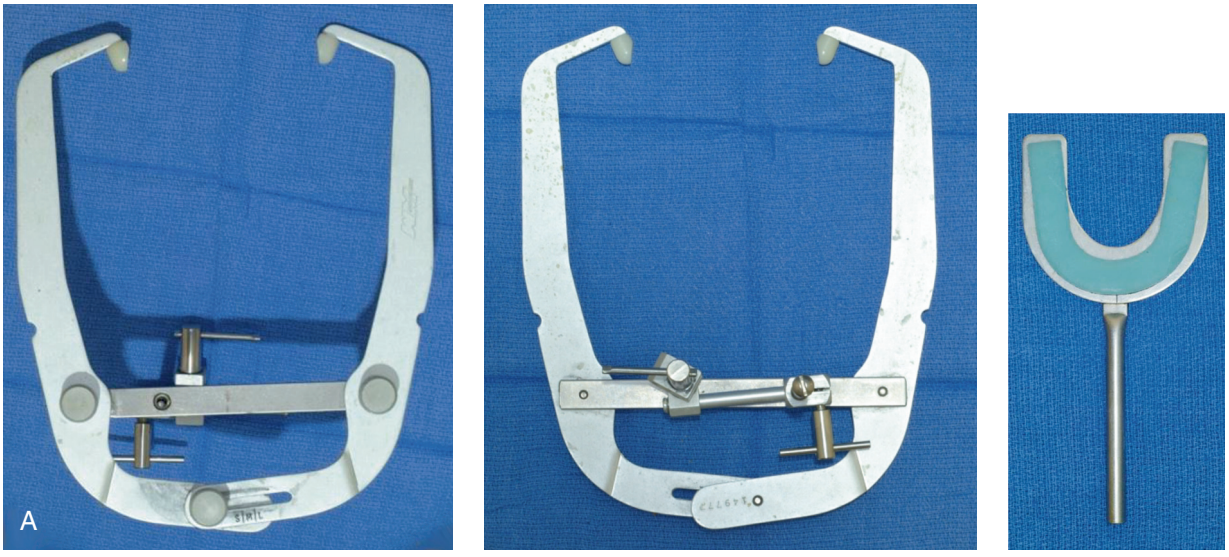


Wax wafer

Bite registration

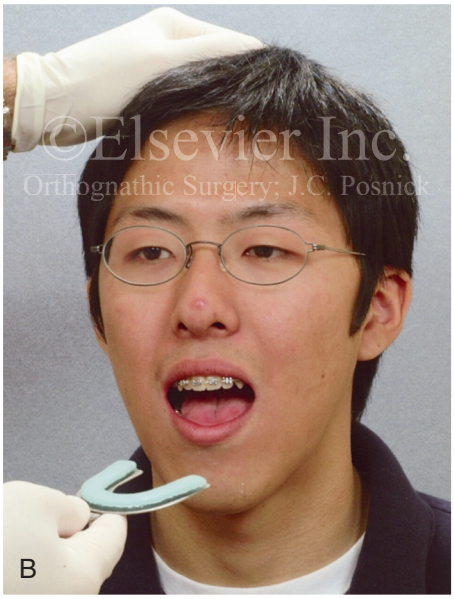
• **Figure 13-2, cont'd C,** Wax wafer before and after bite registration.

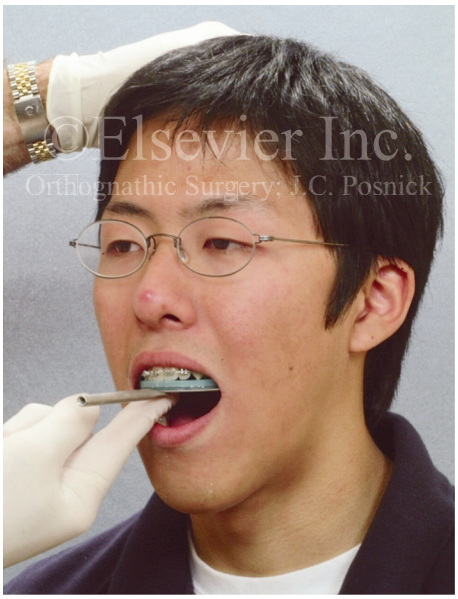
Face-bow registration → For transfer of relationships to articulator



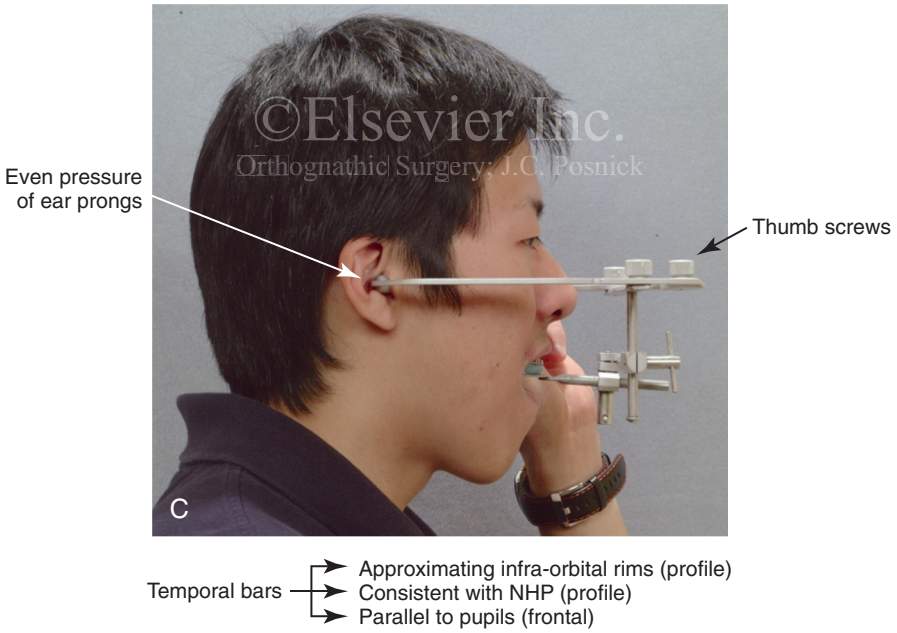
Register spacial orientation between → Condyles/ear canals
Maxilla/maxillary occlusal plane
Skull base/facial plane

• **Figure 13-3 A,** Bite fork with soft wax placed on the upper side is demonstrated. The face-bow apparatus is shown from both the bird's-eye view and the worm's-eye view.



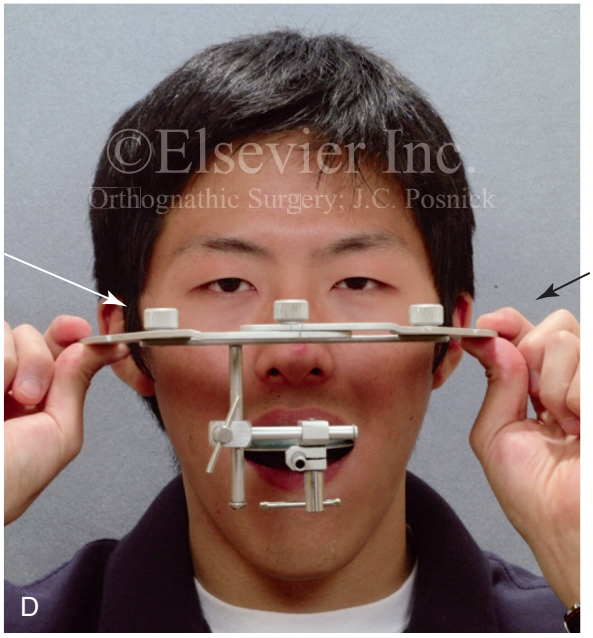


Register patient's maxillary occlusion into soft wax on bite fork

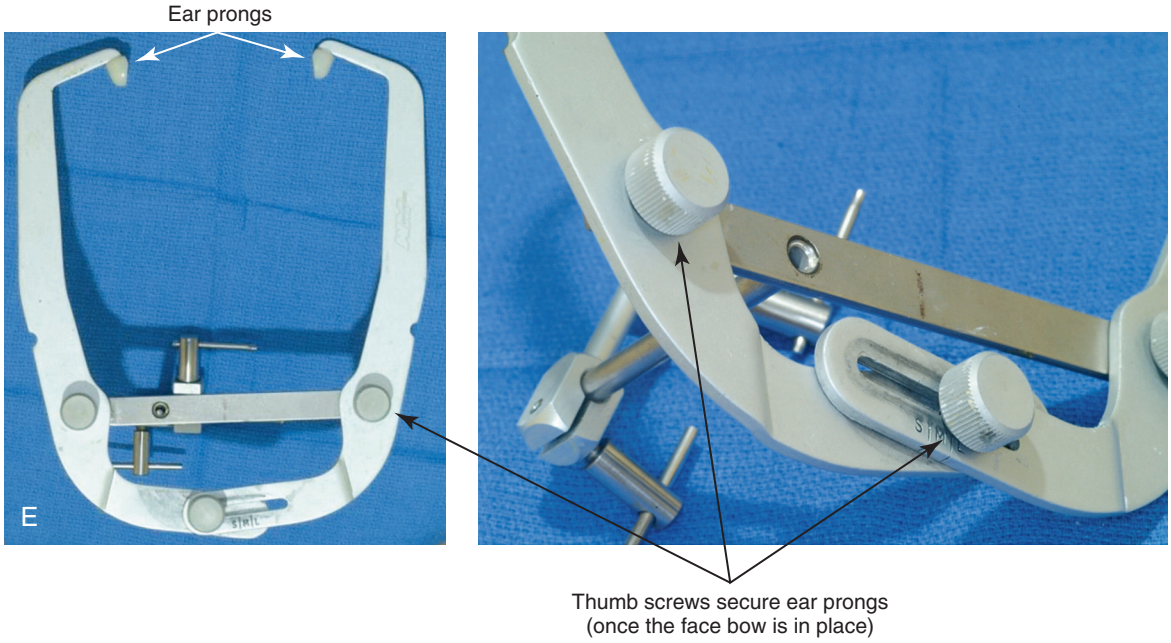


• **Figure 13-3, cont'd** **B,** The patient's maxillary occlusion is registered into soft wax on the bite fork. **C,** The face bow apparatus is held in place through even pressure of the ear prongs in each ear canal. The three thumbscrews are then tightened.

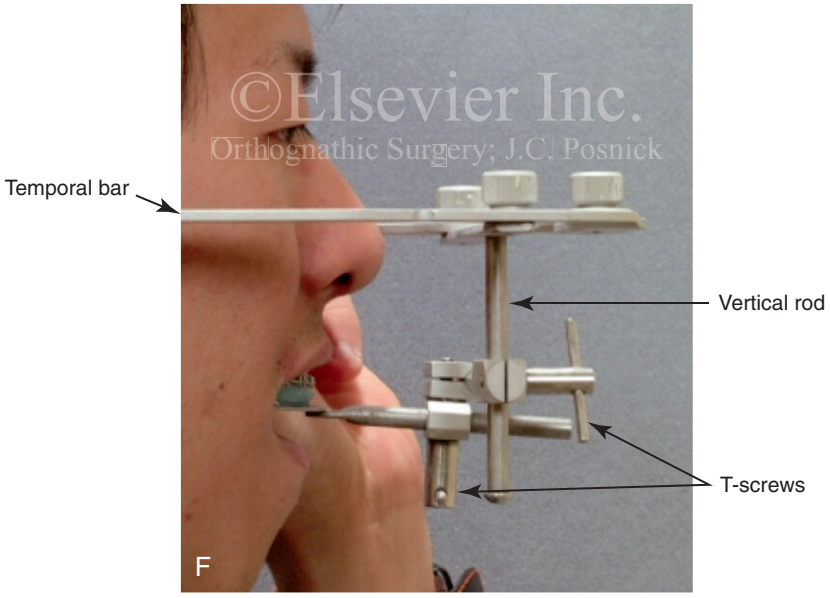
Continued



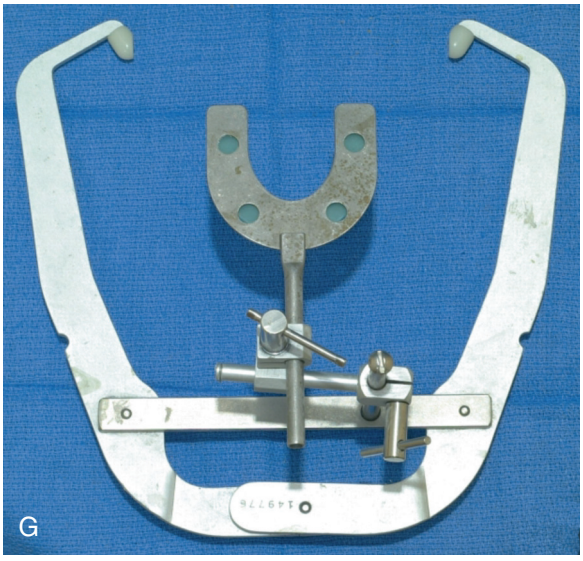
©Elsevier Inc.
Orthognathic Surgery; J.C. Posnick



• **Figure 13-3, cont'd D,** The temporal bar is set parallel with the interpapillary line and consistent with the natural head position. **E,** A close-up view is shown of the thumbscrews that secure the ear prongs in place.



T-screws secure bite fork to vertical rod of face bow



Face-bow apparatus removed from patient
Ready to place on semi-adjustable articulator

• **Figure 13-3, cont'd F,** T-screws secure the bite fork to the vertical rod of the face-bow apparatus. The T-screws are turned clockwise to secure the face bow after confirming that the temporal bar extensions are parallel to the interpupillary line (frontal view) and consistent with the natural head position (profile view). **G,** With the T-screws tight, the thumbscrews are loosened to release the face-bow apparatus from the patient. The face bow is now ready to place on the articulator.

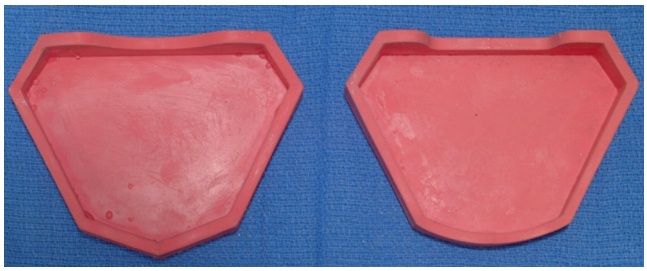
Continued

Alginate impressions of mandible and maxilla

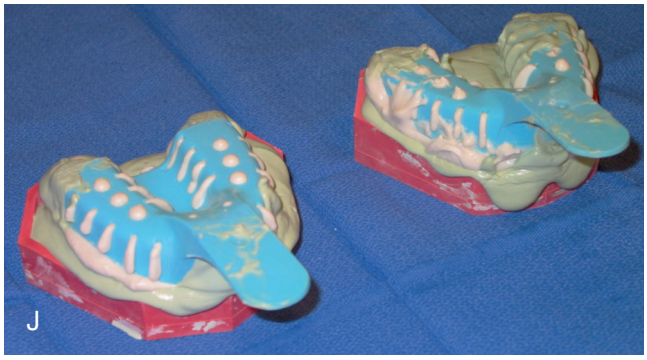
Use vibrator to limit air bubbles

Pour up alginate impressions in green dental (die) stone

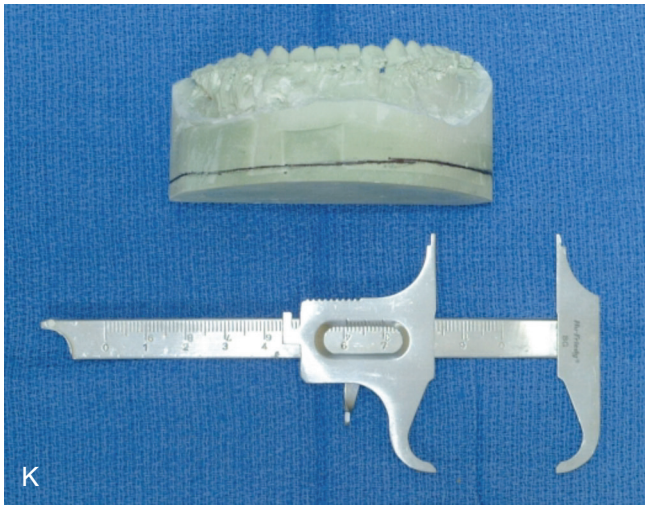
• **Figure 13-3, cont'd H,** Impression trays are selected to fit the patient's arch form. The alginate is mixed, placed in the trays, and then taken to the maxillary and mandibular arches, in turn. Negative impressions of the dentition are recorded in the alginate. **I,** The alginate impressions are "poured up" in green dental (die) stone. The use of a vibrator during this process will limit air bubbles.



Base forms are helpful



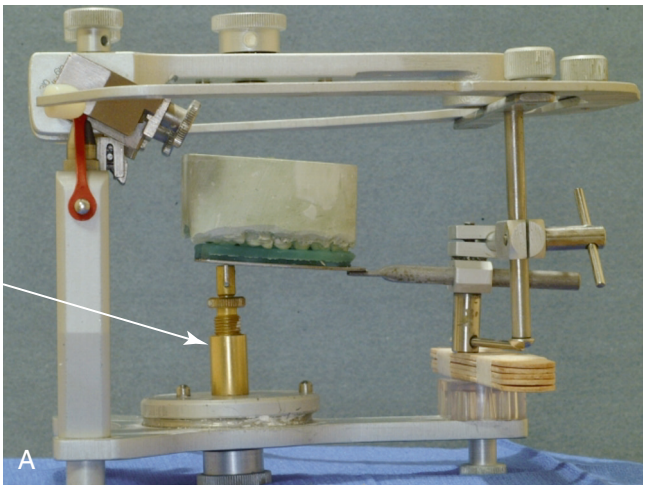
Incorporate at least 30 mm of stone base



Trim each model

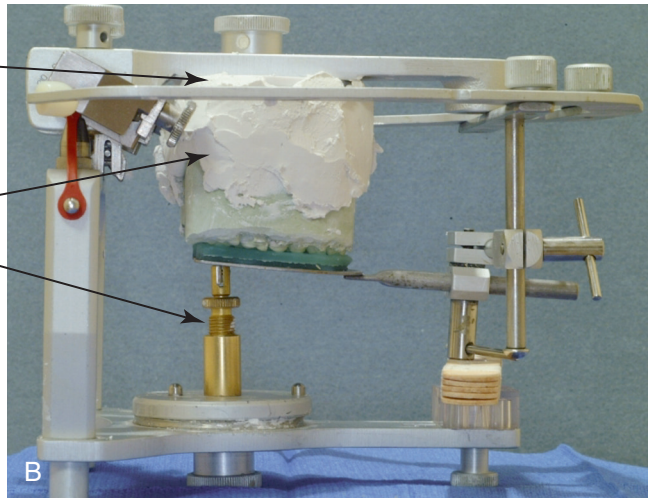
Measure (25-30 mm) down from → First molar cusp tip
→ Canine cusp tip
→ Central incisor cusp tip

• **Figure 13-3, cont'd J,** Base formers are useful when incorporating additional dental stone to achieve at least 30 mm of height for each dental cast. **K,** After the die stone is set (≈30 min), the models can be trimmed to achieve a consistent 25-mm base on the maxillary cast and a 30-mm base on the mandibular cast.

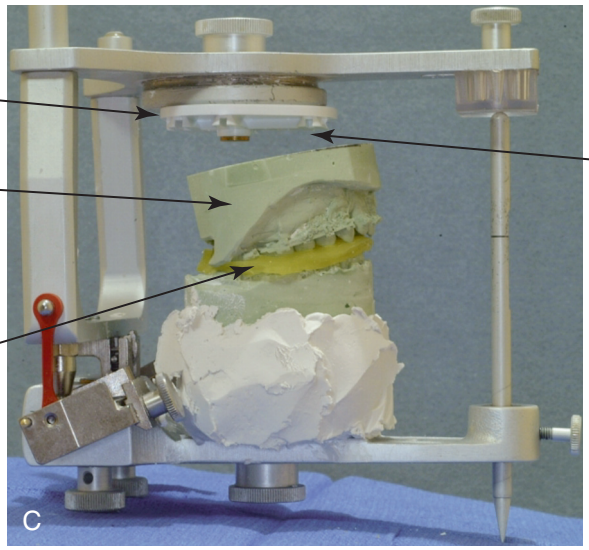


Mounting maxillary cast on articulator using white plaster bite fork support prevents sagging

Base plate

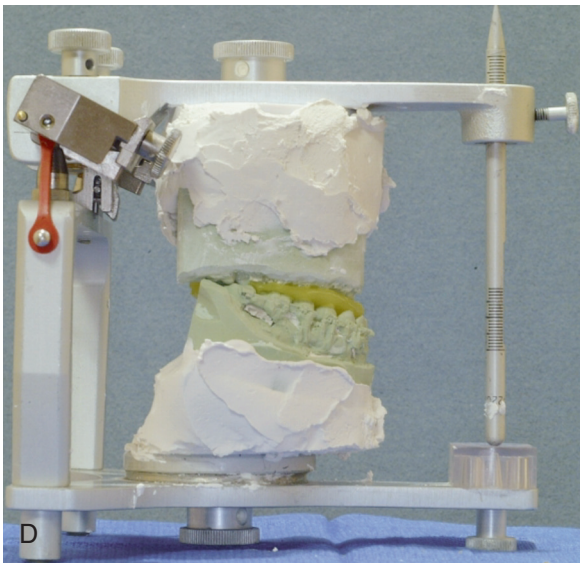


Maxillary cast secured to base plate with plaster



With maxillary unit dry – turn articulator upside down
Use CR wax bite to occlude mandibular cast to maxillary unit

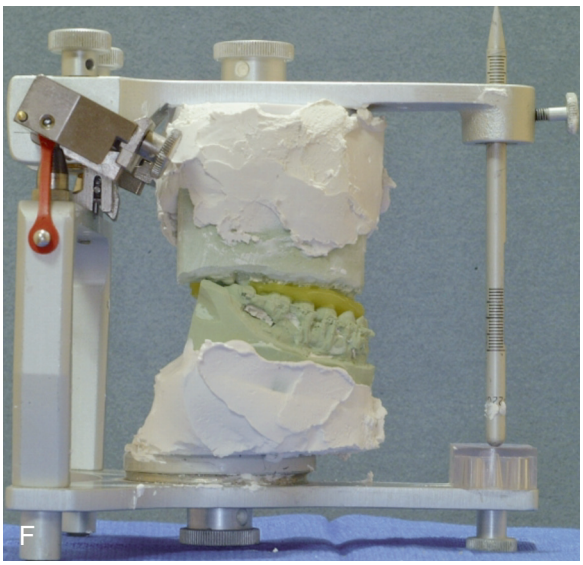
• **Figure 13-4 A,** The trimmed dental casts are then mounted on the semi-adjustable articulator with the use of the face-bow apparatus. The temporal arms of the face bow are maintained parallel to the upper aspect of the articulator and the counter top. Base plates for the maxillary and mandibular units are secured to the articulation. A bite-fork support is useful to prevent the sagging of the face-bow apparatus when mounting the maxillary cast. **B,** The plaster is mixed and added in between the maxillary dental cast and the base plate. **C,** With the maxillary unit initially set (≈15 min), the articulator is turned upside down. The centric relation wax bite is occluded to the maxillary cast. The trimmed mandibular cast is then occluded to the other side of the wax bite.



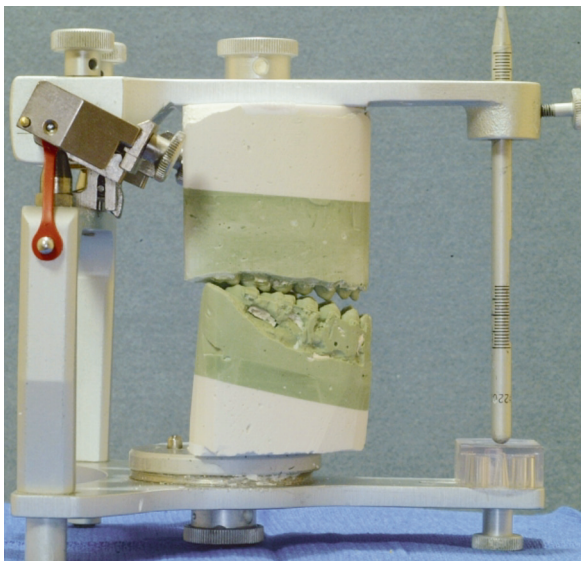
Mandibular and maxillary casts secured to articulator

• **Figure 13-4, cont'd** **D,** With the base plate secured to the articulator, the space that separates the mandibular dental cast from the base plate is filled with white plaster. **E,** The maxillary and mandibular units are removed from the articulator and taken to the grinder for trimming. **F,** The mounted dental casts are shown on the semi-adjustable articulator before and after trimming.

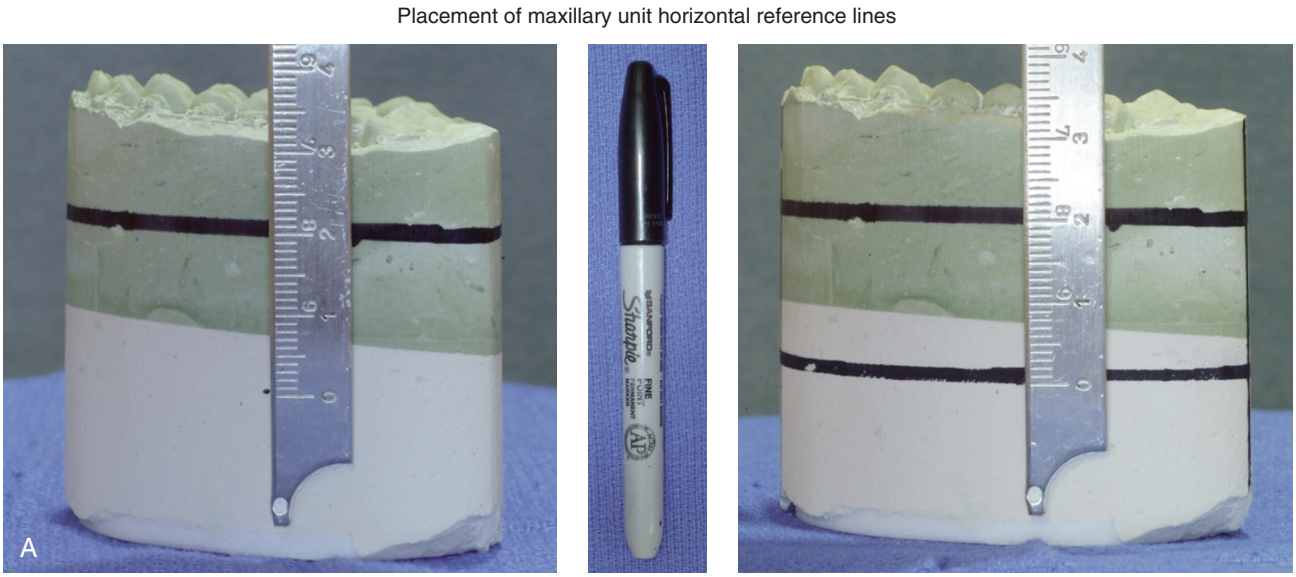
Remove maxillary and mandibular units from articulator, trim each independently on grinder



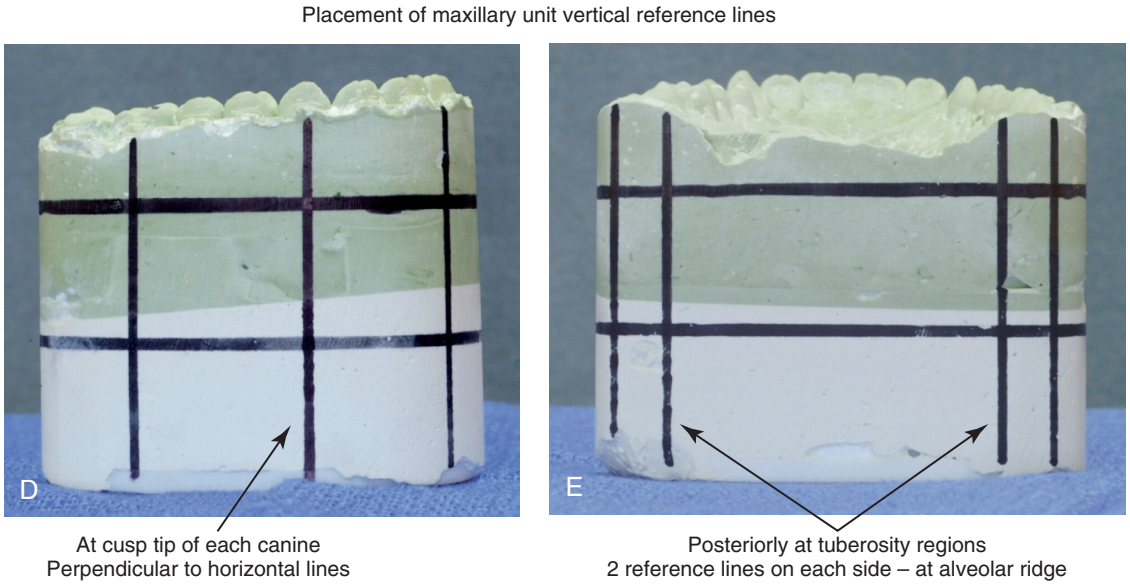
Prior to trimming



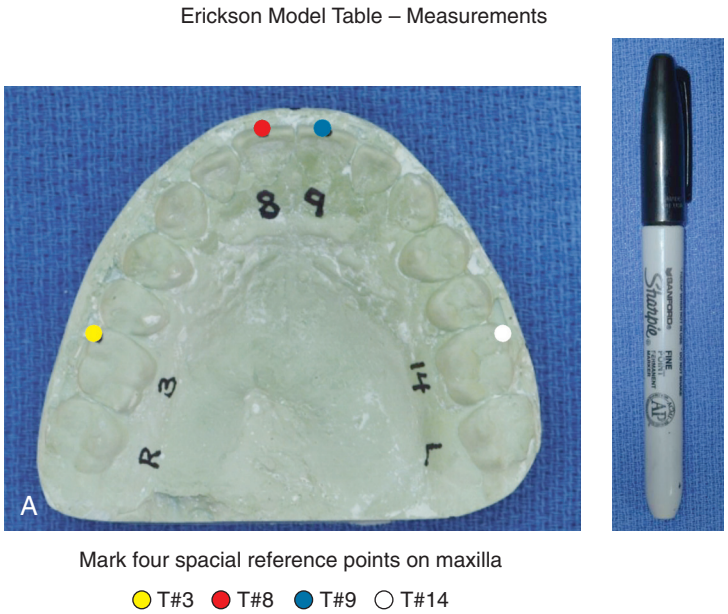
After trimming



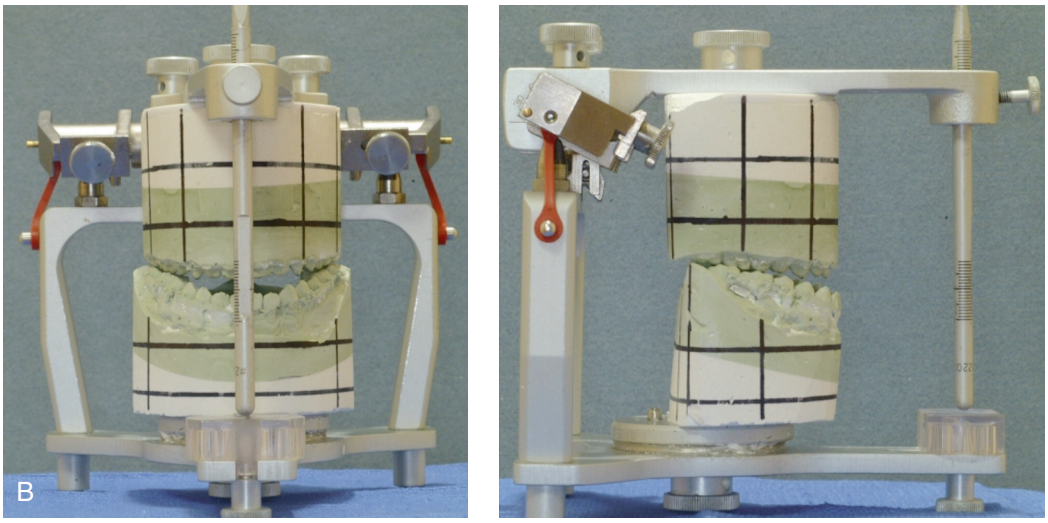
• **Figure 13-5** Marking horizontal and vertical reference lines on the articulated dental casts. **A,** The maxillary unit horizontal reference lines are placed parallel to the base plate. The first horizontal reference line is placed entirely in the green stone. The second is placed entirely in the white plaster, with 15 mm to 20 mm of separation between the lines. **B,** A maxillary unit vertical reference line is placed at the mesiobuccal groove at each first molar, perpendicular to the horizontal lines. **C,** The next maxillary unit vertical reference line is placed between central incisors, perpendicular to the horizontal lines.



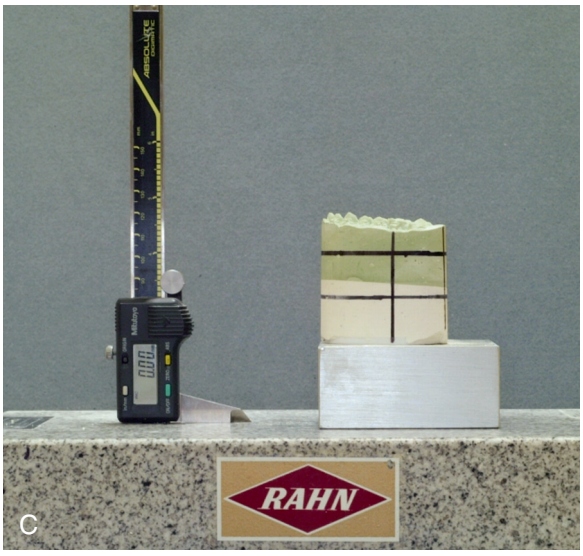
• **Figure 13-5, cont'd** **D,** Additional maxillary unit vertical reference lines are placed at the cusp tip of each canine, perpendicular to the horizontal lines. **E,** Vertical maxillary unit reference lines are also placed posteriorly in the tuberosity regions. Two reference lines are generally placed on each side, adjacent to the alveolar ridges. Similar horizontal and vertical reference lines are placed on the mandibular unit.



• **Figure 13-6** The Erickson Model Table (EMT) is used to register the baseline maxillary orientation in all three planes in space. The baseline measurements are then used to assist with the accurate repositioning and reorienting of the maxilla in accordance with clinical requirements. **A,** With a Sharpie marking pen, a reference dot is placed at the mesiobuccal cusp tip of each maxillary first molar and the midpoint of each maxillary central incisor. *Continued*



Articulated dental casts with reference lines



• **Figure 13-6, cont'd** **B,** The articulated dental casts with horizontal and vertical reference lines already marked are now ready for baseline maxillary reference measurements taken from the EMT. **C,** The maxillary unit is attached to the EMT base mount from which measurements will be made.

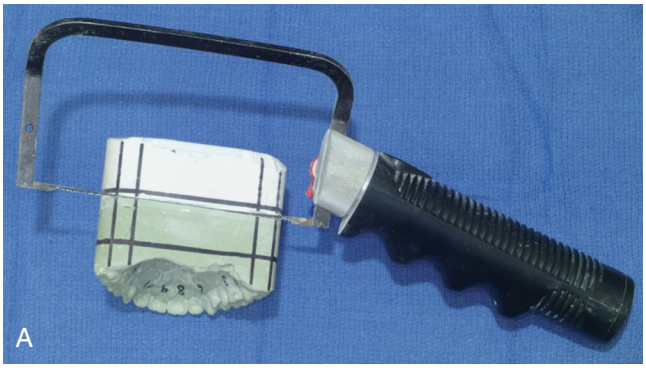
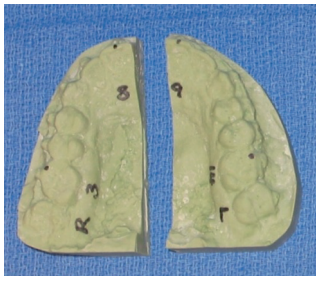
• **Figure 13-6, cont'd F,** The EMT is used to measure the baseline vertical position of each maxillary first molar. This is the distance between the base of the EMT and the mesiobuccal cusp tip of each maxillary first molar. The millimeter number is recorded on the data sheet. The desired vertical surgical change at each maxillary first molar is also written on the data sheet. The final preferred vertical position of the maxillary molars, as a result of model planning, is calculated and recorded. **G,** The EMT is used to measure the baseline transverse midline position of each incisor in millimeters. This is an indication of the maxillary dental midline position from both the right side down and left side down directions. The base measurement is recorded on the data sheet. The desired transverse change at the maxillary incisor is written on the data sheet. The final preferred transverse midline position of the maxillary incisor, as a result of model planning, is calculated and recorded.

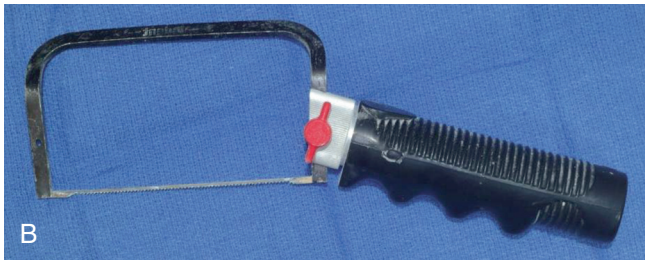


Remove the maxillary unit from the articulator
Then separate the maxillary cast from its base

3–segments?



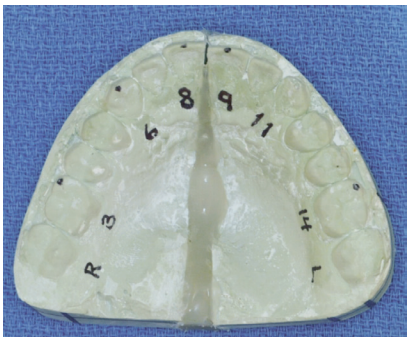
2–segments?



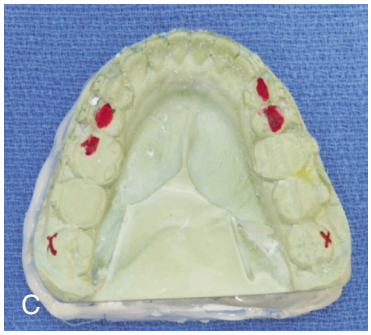
Use die saw to segment maxilla

• **Figure 13-7** The maxillary unit is now removed from the articulator. **A,** The maxillary cast is separated from its base. This is accomplished with the use of a die saw to cut a groove and a knife that is placed into the groove, which is then hit with a hammer. **B,** If indicated, segmentation of the maxillary cast is carried out. This is done in accordance with patient-specific needs to correct the maxillary arch form. Segmentation is generally carried out either as two parts (i.e., between the central incisors and then through the hard palate) or as three parts (i.e., between the lateral incisor and the canine on each side and then through the hard palate). The maxilla is cut by hand with a die saw instrument.

3–segment alignment



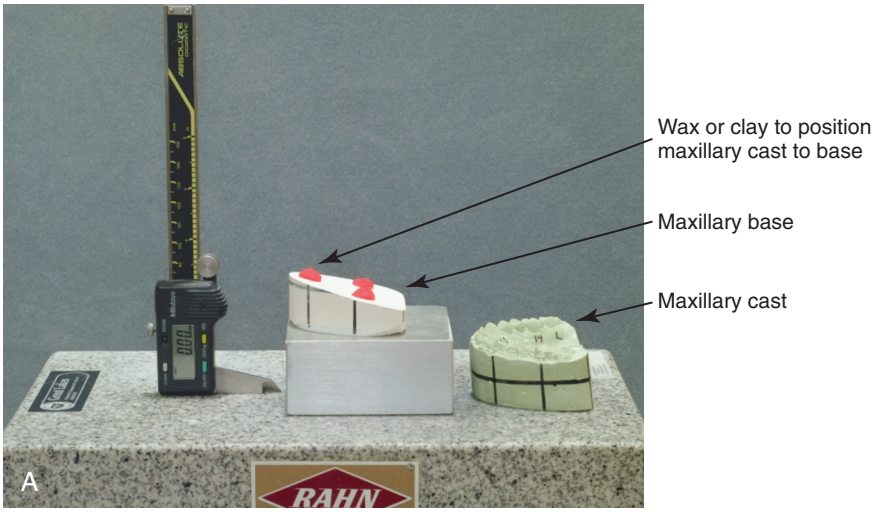
2–segment alignment



Mandibular cast

• **Figure 13-7, cont'd C,** If segmentation of the maxillary cast is required, the cut segments are placed into the corrected arch form by aligning the segments over the mandibular arch. It is important to maintain a physiologic orientation of the interdental papilla, with tight contact between the teeth. Ideally, the adjacent roots are also parallel, with minimal divergence. The maxillary segments are secured together in the corrected arch form with the use of hot glue from a glue gun.

NOTE: If occlusal equilibration is required to achieve the preferred articulation, it is completed on the casts and recorded at this time. The actual occlusal equilibration procedure is completed during surgery.



Maxillary cast is repositioned on maxillary base according to clinical assessment/surgical plan

• **Figure 13-8 A,** The maxillary cast is next repositioned and reoriented on the maxillary base in accordance with the clinical assessment and the surgical plan. The Erickson Model Table (EMT) is used to ensure the correct spatial reorientation of the maxillary cast to achieve the clinical objectives.

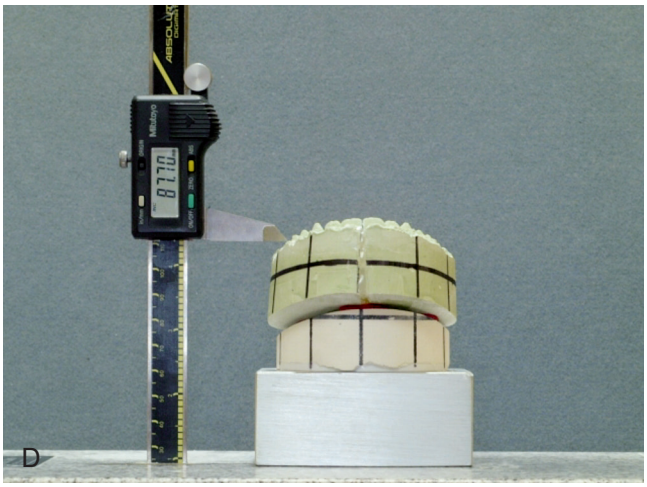
Maxillary vertical change at incisal edge (no change)

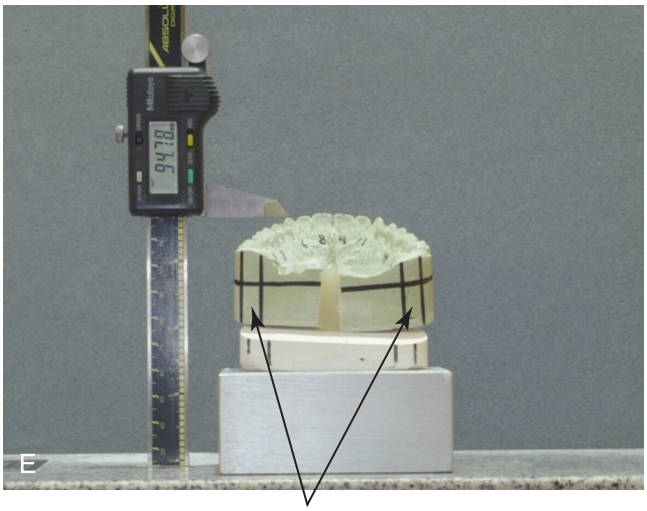
• **Figure 13-8, cont'd B,** The EMT is used to accurately reposition the maxilla. For this patient (see Fig. 13-1), the maxillary horizontal change at the incisal edge is a 5-mm advancement. **C,** In this case, the EMT also confirms that no vertical change will occur at the maxillary incisal edge.



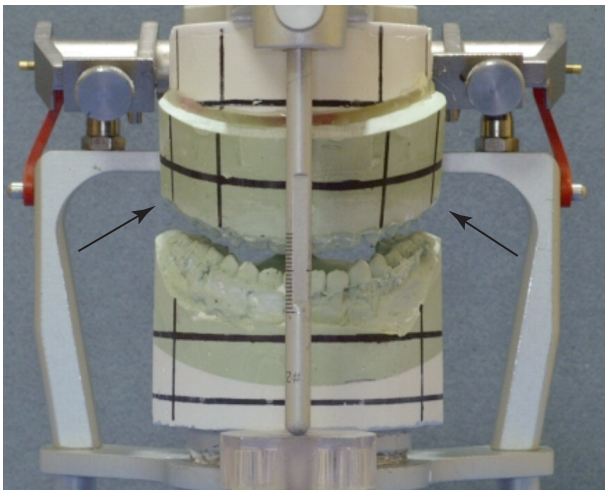
Maxillary Posterior Vertical

	Baseline (mm)	Change (mm)	Final
Right #3	93.1	−3/−1	89.1
Left #14	91.7	−3/+1	89.7

- Maxillary plane change
  - − 3.0 mm vertical (plane) change at right 1st molar
  - − 3.0 mm vertical (plane) change at left 1st molar
- Maxillary cant correction
  - − 1.0 mm vertical (cant) change at right 1st molar
  - + 1.0 mm vertical (cant) change at left 1st molar



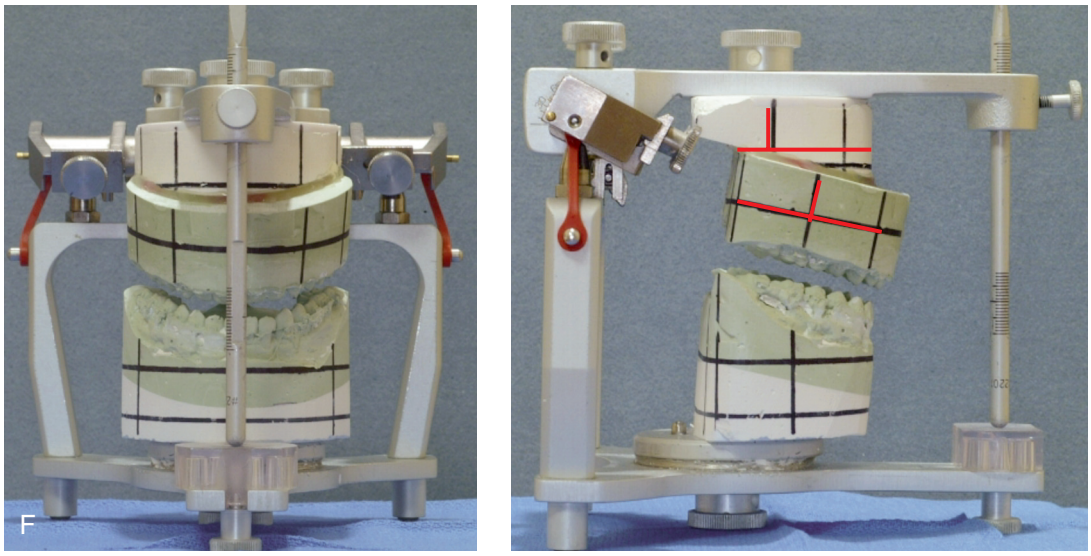
Equal change at both tuberosities
to avoid altering in yaw orientation



Check "yaw" effect
at the occlusal level!!

• **Figure 13-8, cont'd** **D,** The EMT is used to accurately reposition the maxilla at the molars. The confirmation of correct positioning at the mesiobuccal cusp tip of each first molar is essential. The vertical change incorporates the desired three-dimensional roll and pitch changes. **E,** When repositioning the maxilla, the EMT is useful to check for any yaw effect. Establishing equal side-to-side changes at both tuberosity regions is required to avoid a yaw change of the posterior maxilla. The reoriented maxillary unit is placed back onto the articulator for viewing.

Continued



Desired A-pt B-pt alteration to enhance aesthetics (3 mm clockwise rotation of maxilla)

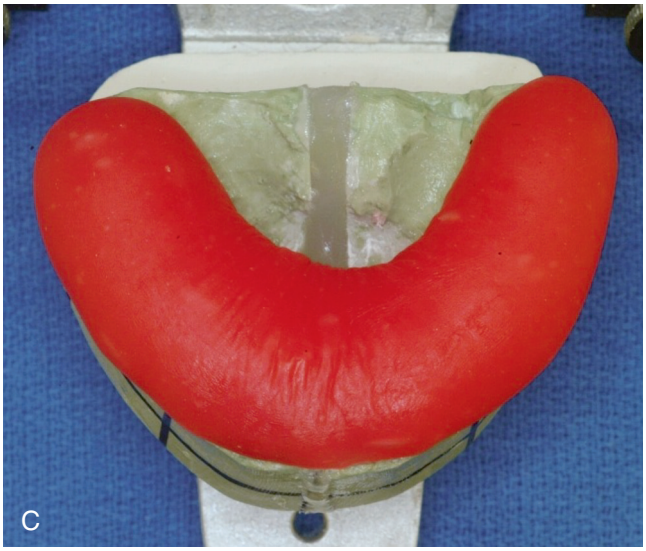
• **Figure 13-8, cont'd F,** The vertical pin on the articulator should remain neutral throughout the process.

NOTE: Before going forward with intermediate splint construction, confirming the yaw orientation of the maxilla relative to the mandible is essential.

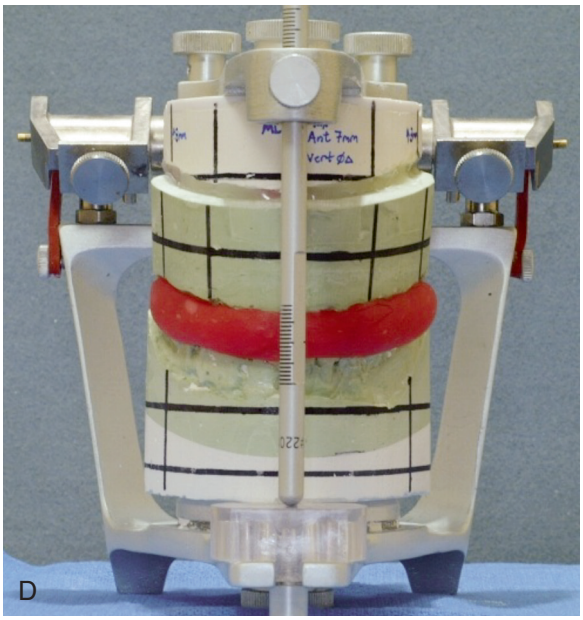
Apply Vaseline to maxillary and mandibular teeth

Use pink acrylic liquid and resin powder

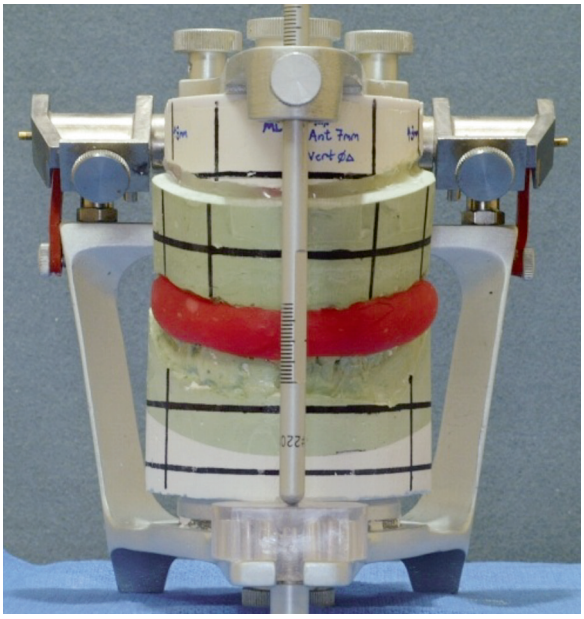
• **Figure 13-9** Construction of the intermediate splint. **A,** Apply a thin coat of Vaseline to the maxillary and mandibular teeth. **B,** Use pink acrylic liquid and orthodontic resin powder, and mix them until the mass does not slump.



Adapt mass to the maxillary occlusal surface



- Close articulator until pin touches
- Mandibular occlusal imprint will result

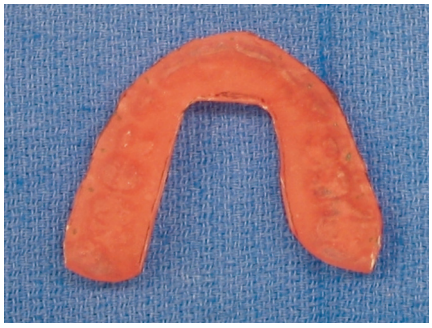


Carefully trim soft acrylic with scissors

• **Figure 13-9, cont'd** **C,** Roll the mixed acrylic mass into a log shape. Adapt the mass to the maxillary occlusal surface. **D,** Close the articulator until the vertical pin touches in a neutral location. A mandibular occlusal surface imprint will result. **E,** Limit "undercuts" from brackets by carefully trimming the soft acrylic with scissors.

Continued

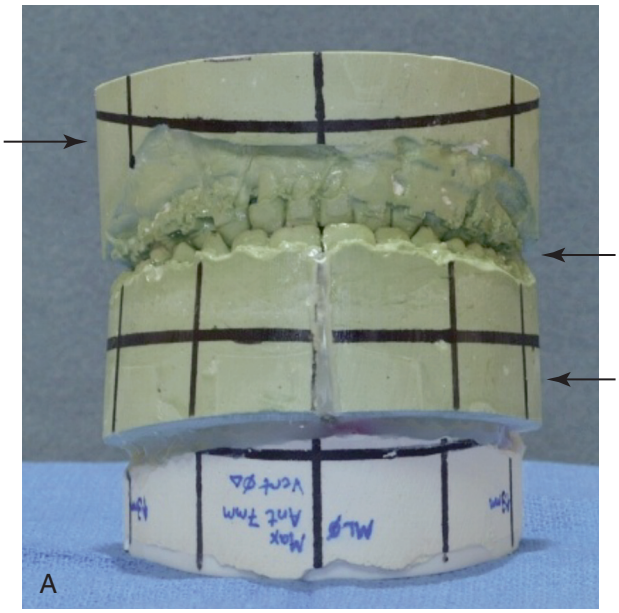
Use lathe to trim excess hardened acrylic



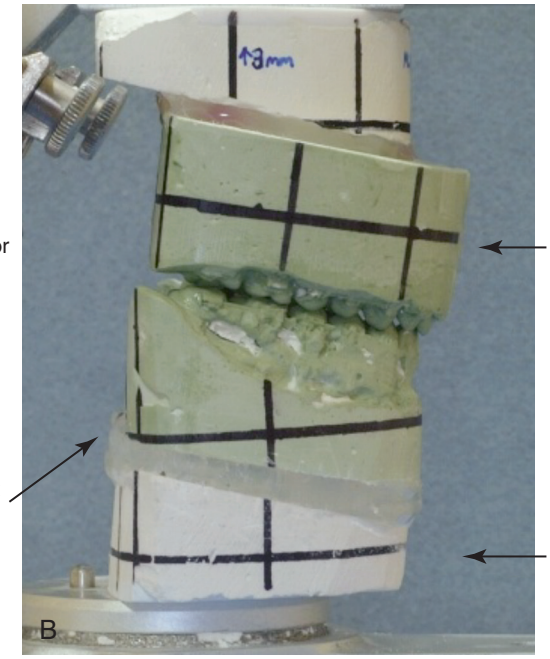
Maintain adequate strength!

Use Dremel drill (acrylic burr) to trim excess hardened acrylic

• **Figure 13-9, cont'd F,** When the acrylic is dry, use a lathe to trim excess hardened acrylic. Maintain adequate strength of the splint to prevent bowing or breakage during surgery. **G,** Use a rotary drill (e.g., a Dremel drill) with an acrylic bur to further trim excess hardened acrylic.



Remove maxillary unit from articulator
Separate mandibular cast from plaster base
Articulate mandibular cast to maxillary unit in "final" occlusion

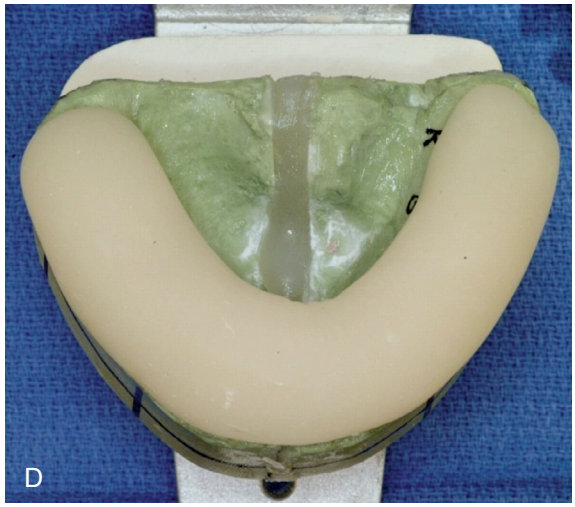


Secure mandibular cast to base with hot glue
Then separate max/mand casts and confirm "final" occlusion

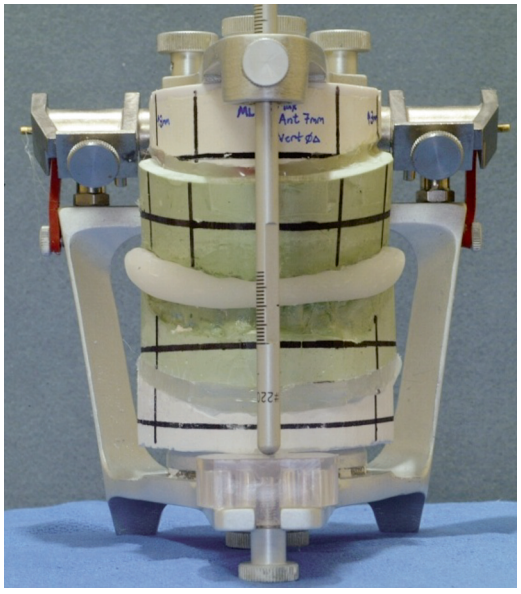
• **Figure 13-10** Construction of the final splint. **A,** Remove the maxillary unit from the articulator. Separate the mandibular cast from the plaster base as previously described for the maxillary unit (see Fig. 13-7, *A*). Next, articulate the mandibular cast with maxillary unit in the final desired occlusion. Secure the final occlusion with hot glue from a glue gun. **B,** Secure the mandibular cast back to the base with the use of either hot glue from a glue gun or white plaster. Maintain the articular pin in a neutral position to achieve this objective. It is generally necessary to remove as least some plaster from the mandibular base during this process; only then is the hot glue or additional plaster used to secure the mandibular cast back to the base. The dried glue that secured the occlusion together is now released. The desired occlusion is confirmed to be accurate before the construction of the final splint.

Continued

Use clear acrylic liquid and resin powder

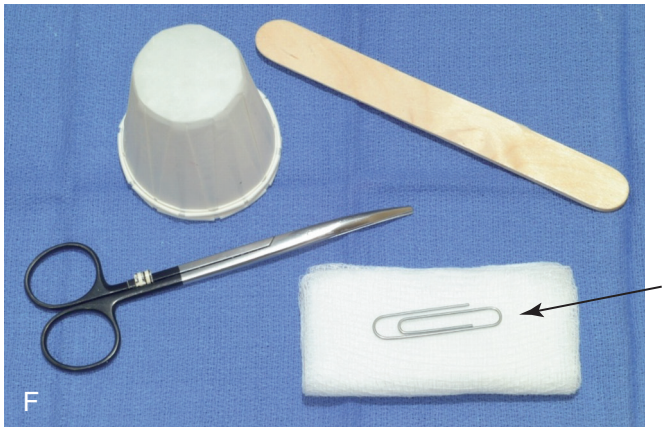


Adapt mass to the maxillary occlusal surface

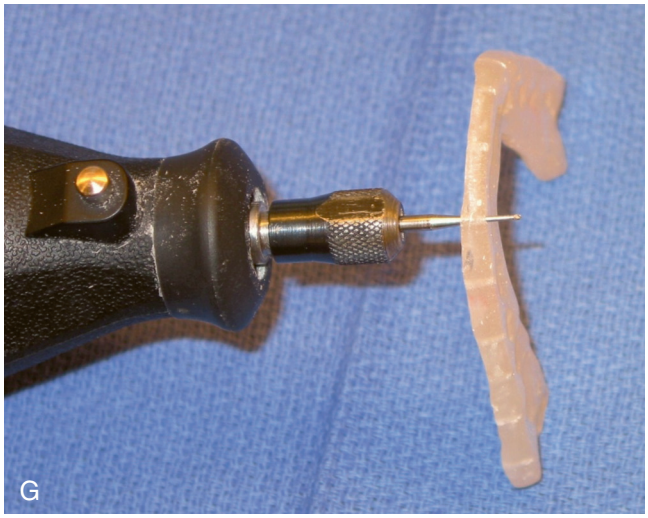


Trim soft acrylic with scissors

• **Figure 13-10, cont'd C,** Use clear acrylic liquid and orthodontic resin powder for the final splint. Mix the two together until the mass does not slump. **D,** Roll the mixed acrylic mass into a log shape. Adapt the mass to the maxillary occlusal surface. **E,** Close the articulator until the vertical pin touches in a neutral position. The mandibular occlusal surface will imprint into the acrylic as a result. Limit "undercuts" from the brackets by carefully trimming the soft acrylic with scissors.



Use additional acrylic to place wire
to reinforce palatal aspect of splint as needed



Drill holes (1.0-mm diameter) in both intermediate and final splints

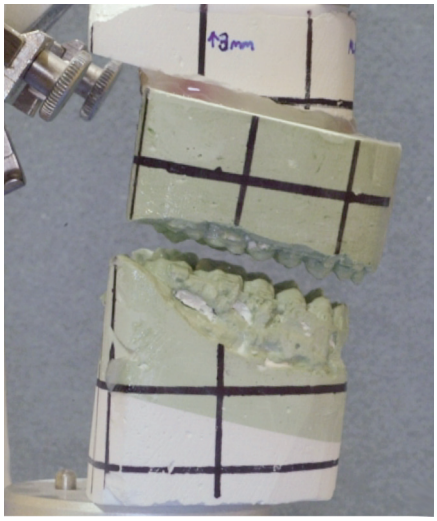
Polish splints on lathe

• **Figure 13-10, cont'd F,** Use additional acrylic to place a metal wire, if needed, to reinforce the palatal aspect of splint. This will prevent bowing or breakage of splint when segmental osteotomies are carried out and when extensive arch expansion is required. **G,** Use a lathe and a rotary drill (e.g., a Dremel drill) to trim excess acrylic from the hardened final splint. Next, place each splint (i.e., intermediate and final) in turn on the maxillary cast, and determine the best location and direction for each interdental drill hole. Complete 1-mm drill holes with the use of a rotary drill (e.g., a Dremel). **H,** Polish the splints on a lathe with the use of a cloth buffing wheel (i.e., pumice and Acrilustre) (Robert Bosch, 1800 W. Central Road, Mt. Prospect, IL).

Intermediate splint

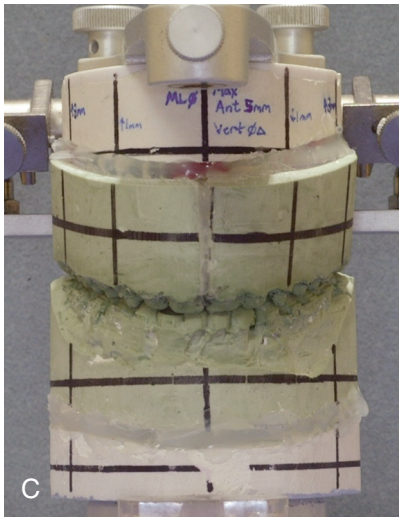
Final splint

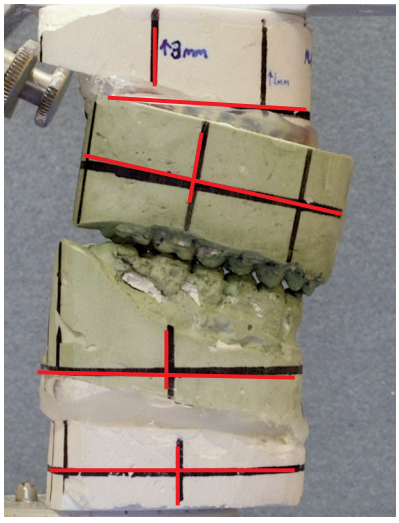
Preoperative articulated casts



Maxilla repositioned

Maxilla and mandible repositioned





Articulated dental casts after analytic model planning

• **Figure 13-11** Dental casts on the semi-adjustable articulator to demonstrate model planning and a view of the finished splints. **A,** Intermediate and final splints finished and ready for use. **B,** Lateral views of articulated dental casts first mounted in a centric relation bite and then after maxillary and final mandibular repositioning. **C,** Frontal and side views of articulated dental casts demonstrating model planning. In this case, note the extent of the maxillary clockwise rotation (3 mm) needed to achieve a preferred A-point to B-point relationship and also to overcome the procumbency of the maxillary incisors.

presurgical clinical examination, is one of the essential steps to avoid unintended errors.[10,28-35,42,43,49,58,60,64,65,71-76,82]

Controversies Surrounding Model Planning for Orthognathic Surgery

Articulator and Face-Bow Device Options

Face bow devices were developed in conjunction with *simple and semi-adjustable hinge articulators* to assist with the registering of the maxillary arch position in relation to the axis of the condylar hinge in three planes of space. The mechanics of the *face-bow device* require a tripod localization. This includes two posterior references to approximate the temporomandibular joints and then an anterior point to relate the maxillary cast three dimensionally to a selected horizontal *facial reference plane*. The posterior reference points that are generally used are the external auditory canals. The anterior point is often aligned with the orbitale (i.e., the infraorbital rims). Selection of the anterior point (e.g., the orbitale) governs the *horizontal facial reference plane*. This will in turn affect the steepness of the recorded maxillary occlusal plane on the articulator; this is discussed later in this chapter.

For orthognathic surgery, analytic model planning typically involves the use of an articulator that provides an approximation of the anatomic relationship between the hinged axis and the incisors. This type of articulator mechanism is designed to approximate the individual's actual mandibular autorotation. This is especially important for bimaxillary surgery, when autorotation of the maxillomandibular complex helps to dictate the position of the maxilla before the mandibular osteotomies are completed. Marko conducted research to demonstrate that the mathematical difference in the horizontal projection achieved when such advancement is carried out in combination with a maxillary impaction of 5 mm is significantly affected by the type of articulator that is used.[46] An average error of 2 mm was found with use of the Galetti articulator *(simple hinge),* whereas only 0.2 mm of error occurred with the Hanau articulator *(semi-adjustable)*.[46]

NOTE: The use of a semi-adjustable articulator in bimaxillary surgery will be more accurate and is therefore preferred to the use of a simple hinge articulator.

O'Malley and Milosevic compared three face-bow semi-adjustable articulator systems to measure any differences in the recorded steepness of the occlusal plane that was produced.[52] The three articulators studied were the Dentatus type ARL; the Denar MkII; and the Whip Mix Quickmount 8800. The recorded measurement of the steepness of the occlusal plane was taken as the angle between the face-bow bite fork and the horizontal arm of the articulator. This measurement was then compared with the angle of the maxillary occlusal plane to the Frankfort plane as measured via lateral cephalometry. Of the three semi-adjustable articulators tested, the Whip Mix Quickmount 8800 came closest to achieving the maxillary occlusal plane (with respect to the Frankfort plane) as measured via lateral cephalometry; it flattened the occlusal plane by only 2 degrees ($P < .05$). The results of the Dentatus and Denar MkII articulators demonstrated flattening of the occlusal plane by 5 degrees and 6.5 degrees, respectively. Ellis also demonstrated how commonly used methods of face-bow registration may erroneously capture the spatial relationship of the maxilla with the Frankfort horizontal plane.[18] This is likely to be problematic if the surgeon intends to use the Frankfort horizontal from the patient's cephalogram as the reference plane from which facial aesthetic objectives will be planned.

A critical step in model planning is the accurate recording of the relationship (i.e., angle and orientation) between a *designated facial plane* and the *maxillary occlusal plane*. As stated, capturing this orientation is accomplished with a face-bow device that is used in the clinic setting. (Note: I use the #8645 Quick Mount Face-Bow, Whip Mix Products, Louisville, KY.) The face-bow registration is then transferred to the semi-adjustable articulator for the mounting of the maxillary model. (Note: I use the #8500 Articulator, Whip Mix Products, Louisville, KY.)

I prefer to judge the desired facial (surgical) change (i.e., horizontal, vertical, roll, pitch, and yaw) and register the face bow from the *natural head position (NHP)* rather than the *Frankfort horizontal plane*.

I prefer to use the NHP orientation as it is the same view from which aesthetics of the face are typically judged by others at conversational distance. Many clinicians prefer to plan angular and linear surgical change for the patient's face from the Frankfort horizontal plane rather than the NHP. If this is done, the surgeon should register the face bow as precisely to the Frankfort line (i.e., the line between the porion and the orbitale) as possible. He or she should then meticulously attempt to mount the cast to match the orientation of the maxilla with that of the Frankfort horizontal plane.

NOTE: The importance of the face-bow semi-adjustable articulator system to the process of accurately capturing the occlusal plane with respect to Frankfort plane orientation is only relevant if the surgeon is planning facial aesthetic changes according to a strict cephalometric analysis (i.e. that also depends on Frankfort plane orientation).

Centric Relation: Definition and Capture

Definition of Centric Relation

In 1987, the definition of CR underwent a change in terminology from being considered a mandibular position in which the condyles are seated in the most "posterior

superior" position to one in which they are placed in the most "superior anterior" position in the glenoid fossa.[72] For analytic model planning in preparation for orthognathic surgery, defining the position of the condylar head during mandibular protrusion and lateral excursions is not critical. However, it is essential to locate a mandibular position that is reproducible with the teeth in occlusion. This must be obtained without the assistance of the patient (i.e., with fully relaxed masticatory muscles), and it needs to be reliably accomplished both preoperatively in the clinical setting and intraoperatively with the patient under anesthesia. This position of the mandible with the teeth in occlusion is usually registered in wax (i.e., a wax bite) and then transferred to the articulator. This is an important step for analytic model planning to be accomplished accurately.

An erroneous inconsistent recording of CR will lead to the malpositioning of the maxilla or mandible during surgery. A survey study conducted by Truitt and colleagues confirmed that 98% of oral and maxillofacial surgeons define CR as the most posterior superior positioning of the mandible.[79] Interestingly, a majority of the orthodontists surveyed agree with the surgeons' definition of CR, but there was less consistency.[79] According to the survey, surgeons and orthodontists do agree that dental casts of the teeth for orthognathic planning should be mounted in CR.

Capturing of Centric Relation

Hellsing and McWilliam used a *subtraction technique* to assess the repeatability of the CR recorded with a *one-handed push-back technique*.[31] They found that the mandibular condyles can be seated in a reproducible position, which is well suited for the registration of CR. Campos and colleagues compared the *swallowing technique* with the *chin-point guidance technique* with the patient in both upright and supine body positions and found that both techniques established a physiologic CR in a reproducible manner.[86] Interestingly, when the chin-point guidance method was used, the work of these authors suggested that reliability was greater with the patient in the upright, seated patient as compared with the supine position.

Simon and Nicholls compared the chin-point guidance, *chin-point guidance with ramus support,* and *bimanual manipulation* techniques.[68] They found that there were no significant differences in the range of mandibular positions that were observed. Interestingly, their study patients did not include individuals with jaw deformities. It is known that patients with specific patterns of jaw deformity (e.g., Class II mandibular retrognathism) are more likely to involuntarily posture the mandible forward during the swallowing technique.[32,33]

The *chin-point guidance technique* is accomplished by using one hand to apply pressure to the subject's chin and the other hand to apply counter pressure to their occiput. This allows the surgeon to apply posterior and superior "vectored" force to the anterior aspect of the mandible. By doing so, the condyles will be positioned in a superior-anterior location within each glenoid fossa (i.e., CR) (see Fig. 13-2).

NOTE: I find the *chin-point guidance technique*—when used both preoperatively in the clinic setting and intraoperatively by the same surgeon—to be both reliable and convenient for the orthognathic surgery patient. This is the method that I have adopted and that I use successfully in clinical practice.

Bite Registration Material

The material used to record CR (e.g., soft wax) is also considered as a potential source for the introduction of error. Adrien and Schouver studied mandibular model-mounting errors; they demonstrated that wax can create error and that the error is directly proportional to the wax's thickness.[2] They suggest that the wax between the approximating teeth be as thin as possible. In addition, the wax should not be punctured, because this may result in sliding from CR to centric occlusion (CO). The wax should also retain its rigidity to avoid the distortion of contact points. The wax bite must be protected after it is removed from the mouth, because it is easily deformed. Ideally, it is used without significant delay to the time that the models are mounted on the articulator (see Fig. 13-2).

Inaccuracies of Osteotomy Site Measurements when used in Isolation to Reorient the Maxilla in Bimaxillary Surgery

The *face-bow device* is used to spatially orient patients' dental models on a *semi-adjustable articulator*. The belief that measurements may then be made at the equivalent of the Le Fort I osteotomy site to accurately reposition or reorient the maxillary cast on the articulator without the use of the *Erickson Model Table* is flawed. The errors of this model surgery and splint-construction approach would then be further compounded if the surgeon relied on actual Le Fort I osteotomy site measurements during operation as a gauge of where to reorient the maxilla without the assistance of *external facial reference landmarks* and measurements.[13,28,36,40,41,53,56,57,59,69] The use of these methods (i.e. osteotomy site measurements) to reposition the maxilla in the dental laboratory before splint fabrication and then during surgery before plate and screw fixation may work for uncomplicated movements (e.g., limited horizontal and vertical repositioning), but it is likely to become grossly flawed when trying to accomplish complex yaw, pitch, and roll orientation changes of the midface.

Accuracy of Current Analytic Model-Planning Techniques to Achieve Desired Results

The *Erickson Model Table* is a device that is used to document the baseline three-dimensional orientation of

the mounted maxillary model on the semi-adjustable articulator. (Note: I use the Erickson Model Block and Platform Model Measuring Kit designed by Great Lakes Orthodontics Products, Tonawanda, NY.) The Erickson Model Table is then used to assist the three-dimensionally reposition and reorient the maxillary cast to the desired facial (surgical) change.[19,20] The reoriented maxillary model on the articulator is then used to construct the intermediate splint. In the operating room, the use of the *prefabricated intermediate splint* in conjunction with precise *measurements of the anterior vertical dimension of the midface* (e.g., direct vertical measurement from the medial canthus to the maxillary incisor on each side of face) has eliminated many of the inaccuracies that were previously experienced during model planning and surgical execution (see Fig. 13-6, *C*).[20,27,36,40,41,51,53,56,57,66,81]

Interestingly, the few studies published in the literature show a wide range of variation between what was planned by the clinician before surgery and what is then actually achieved during operation with reference to the advancement of the maxilla after Le Fort I osteotomy during bimaxillary surgery. An exception is the study of **Gil and colleagues,**[28] who completed a retrospective study to evaluate the predictability of maxillary repositioning (i.e., vertical and horizontal change measured at the maxillary incisors) after Le Fort I osteotomy during bimaxillary surgery. They used analytic model-planning techniques, including the following: 1) face-bow transfer 2) the use of a semi-adjustable articulator 3) the use of Erickson Model Table measurements 4) intermediate splint construction and 5) the use of external facial height reference points during surgery. A consecutive series of patients (n = 32) were analyzed, with measurements taken with consistent lateral cephalometric radiographs before and 1 week after surgery.[69] The results indicate less than a 1-mm difference between the planned and the early postoperative results for both vertical and horizontal repositioning in all patients. **Stanchina and colleagues** also carried out a retrospective study to measure the accuracy of external reference points in conjunction with model planning to reposition the maxilla during bimaxillary surgery.[69] The study subjects (n = 41) showed a surprisingly consistent mean difference between predicted and achieved vertical repositioning of the maxilla (0.36 mm; standard deviation, 0.26 mm). Their success with horizontal repositioning was less accurate. The mean horizontal variance was 1.4 mm (standard deviation, 1.63 mm).

NOTE: The reasons for variation between the planned and actual maxillary advancement in most published studies remain unclear. This is because the descriptions of the key steps that they used are generally not fully described.

Review of Key Steps for Successful Analytic Model Planning and Surgical Execution

1. *The direct visual examination of the patient by the surgeon in the clinic setting.* With the use of facial analysis, key measurements of the individual's maxilla in relationship to the upper face (i.e., the forehead, external ears, and orbits) are recorded. These measurements will confirm variations from normal and define the surgical objectives (see Fig. 13-1, *H*).
2. *The use of a face-bow device to record the spatial orientation of the upper face and condyles with regard to the maxilla.* This is generally done with the use of the external auditory meatus for two of the reference landmarks. The anterior aspect of the face bow (i.e., the frontal view) is adjusted to be parallel with the interpupillary line. With the patient's head and neck in the NHP, the lateral aspects of the face bow are then adjusted to orient the temporal arms to be parallel with the floor (see Fig. 13-3 C and D).
3. *The transfer of the spatial orientation of the maxilla to the semi-adjustable articulator.* This is done with the arms of the face-bow and the upper arm of the articulator parallel to the floor (counter top) (see Fig. 13-4 A).
4. *The taking of an accurate CR bite registration of the patient in the clinic setting.* This is then used to orient the dental models to each other on the semi-adjustable articulator (see Figs. 13-2 and 13-4, *C*).
5. *The use of the Erickson Model Table in the dental laboratory to establish the baseline spatial orientation of the maxillary cast* (see Fig. 13-6, *C*).
6. *The use of the Erickson Model Table to accurately reorient the upper jaw model on the articulator into the desired surgical position* (see Fig. 13-8, *A*).
7. *The fabrication of a splint for use during surgery* to achieve the planned maxillary reorientation (see Fig. 13-9)
8. *The use of external facial measurements* (e.g., the distance from the medial canthus to the maxillary incisor) during operation to establish the baseline vertical position of the maxilla within the upper face and then to accurately reorient the upper jaw to achieve surgical objectives (see Fig 15-18, *A*).
9. *The accurate location of the terminal hinge position of the condyles during operation.* This is done to reproduce the position of the condyles when taking the CR bite registration in the clinic setting, and it is essential before rigid fixation is secured across each osteotomy site (see Fig 15-37, *B*).

COMMENT: The surgeon no longer attempts to correlate millimeter changes at the Le Fort I osteotomy site with the expected facial morphologic outcome. When properly executed, the accuracy of analytic model-planning techniques as described for precise orthognathic surgery has been documented. This is discussed in more detail later in this chapter.

The Role of Computer-Aided Software Design and Model Planning

For a variety of reasons, some patients with complex maxillofacial skeletal deformities undergo treatment that achieves suboptimal results. Despite the surgeon's best efforts, it can be difficult to assess the preferred surgical spatial reorientation of the jaws for the achievement of ideal facial projection and symmetry. Although standard analytic model planning (as described in this chapter) has proven to be effective for most orthognathic surgical problems, three-dimensional deformities of pitch, roll, and yaw continue to confound the ability to achieve predictable results in each and every patient. The current standard treatment planning process is also felt to be time consuming and labor intensive, especially for those clinicians who do not evaluate dentofacial deformities and execute orthognathic surgery as significant components of their practice.

Recently, surgeons have begun looking to computer-aided design and computer-aided modeling software to assist with the planning and implementation of orthognathic procedures.[3-5,7,11,23,24,25,45,47,48,61,67,70,83,84] These technologies allow clinicians to import two-dimensional computed tomography data in a digital imaging format at a computer work station and to then generate a three-dimensional representation of the patient's skeletal and soft-tissue anatomy. The data set can be used to mill a stereolithographic model, or it can be manipulated on the computer screen for purposes of analysis and treatment planning. The ability of virtual model planning (as opposed to analytic model planning, as described in this chapter) to routinely achieve an improved end result for the orthognathic patient has yet to be confirmed. It is also unclear whether the higher costs of virtual model surgery planning can be offset by savings in the clinician's time that would otherwise be required for analytic model planning.

A successful orthognathic outcome is often judged by the achievement of a preferred occlusion, an open upper airway, and enhanced facial aesthetics. Any methods that are proven to better achieve these objectives over the long term with efficiency and reliability are welcomed. Unfortunately, current virtual model surgery planning still requires that alginate impressions of the maxilla and mandible be taken, that plaster models be made of the maxillary and mandibular arches, and that ideal occlusion be hand articulated and marked by the surgeon into the set final occlusion. If segmental osteotomies are required, the surgeon must also cut the plaster models and secure them together as required to achieve the set final position. Furthermore, a computer-generated surgical splint has not yet been proven to be fully reliable for complex, double-jaw surgical cases.[11] Problems that remain to be addressed include the following: the identification of internal reference systems; the making of three-dimensional measurements; the management of interferences by metal (orthodontic) hardware; the orientation of computed tomographic models to the NHP; and the necessity of capturing the computed tomography data while the patient is in CR.

Standard Facial Records for Orthognathic Surgery

- Standardized facial and occlusal view photographs
- Lateral cephalometric radiograph
- Panoramic radiograph
- Alginate impressions of the maxilla and mandible
- CR wax bite registration
- Face-bow registration for transfer to a semi-adjustable articulator
- Facial measurements taken via a direct visual examination (Fig. 13-1H).
- Analytic model planning data entry form (Fig. 13-6C)
- Cone-beam computed tomography scanning (patient specific)
- Full-mouth periapical radiographs (patient specific)

Key Measurements Obtained via Direct Visual Examination to Define Planned Maxillary Surgical Change

- Horizontal change at incisors _____ (mm)
- Vertical change at incisors _____ (mm)
- Midline change at incisors _____ (mm)
- Maxillary plane change (total) _____ (mm)

Clockwise—Counterclockwise

- Maxillary cant correction (total) _____ (mm)

  ↑ ↓ _____on right ↑ ↓ _____on left

- Vertical change at T#3 (right) molar ___ + ___ + ___ = ___ (mm) (Base + Cant + Plane)
- Vertical change at T#14 (left) molar ___ + ___ + ___ = ___ (mm) (Base + Cant + Plane)

Face-Bow Registration and Transfer to the Semi-Adjustable Articulator

An 18-year-old recent high school graduate who presented to this surgeon for the evaluation of an uncorrected dentofacial deformity that was characterized as maxillary deficiency with relative mandibular excess is described. He is shown to demonstrate the technique of analytic model planning as typically carried out (see Figs. 13-1, 13-12, and 13-13).

Face-Bow Registration
(see Figs. 13-2, *A*, through 13-3, *G*)

- Place soft wax on upper side of the face-bow bite fork.
- The midpoint between the central incisors (interproximal) should match the center of the bite fork.
- Register the patient's maxillary occlusion into the soft wax on the bite fork.

- Place an ear prong in each ear canal, and hold the temporal extensions with even pressure medially, superiorly, and forward. Tighten the three thumb screws of the temporal extensions.
- In the frontal view, the face bow is initially adjusted to be parallel with the pupils and in proximity to the infraorbital rims.
  - If the orbits are asymmetric (e.g., in a patient with hemifacial microsomia or the Klippel–Feil anomaly), do not use the interpupillary line as a frontal reference plane. Instead, use the NHP as the facial reference plane.
- In the profile view, the face bow is adjusted to be parallel with the floor while the patient is in the NHP.
  - If the ear canals are asymmetric, do not rely on them for face-bow orientation. For example, for a patient with hemifacial microsomia, if the ear canal on one side is not present or is abnormally located, then place the face-bow ear prong in the appropriate position to approximate the contralateral ear canal. The face bow should be parallel with the floor while the patient is in the NHP (i.e., the NHP is the reference plane).

- Firmly hold the bite fork to the maxillary occlusal surfaces (through the soft wax). Pressure is applied to the bite fork by the patient with the use of a thumb from each hand. When this is accomplished, do the following:
  - Loosely connect the bite fork, (which is held firmly to the patients maxillary teeth), to the face-bow apparatus, (which is held in place by the clinician), with the use of the T-screws on the vertical rod.
  - In profile and with the patient in the NHP, adjust the face-bow temporal extensions to closely parallel the floor.
  - Tighten the two T-screws to secure the bite fork to the vertical rod of the face-bow apparatus.
- Now that the face-bow registration is complete, loosen the three thumb screws of the temporal extensions to release the ear prong from each ear canal. Remove the face bow from the patient for transfer to the semi-adjustable articulator.

Take Alginate Impressions, Pour the Impressions in Stone, and Trim the Casts
(see Fig. 13-3, *H* through *K*)

- Take accurate alginate impressions of the maxilla and the mandible.
- Pour the alginate impressions in green stone, and incorporate at least 30 mm of base. Base formers are helpful to accomplish adequate base height. To limit air bubbles, use a vibrator when pouring stone into alginate impressions.

NOTE: The use of stone rather than plaster improves strength, with less porosity and less breakage.

- When the casts are dry (≈15 min), remove the alginate and base former from each stone cast. Measure 30 mm of base on the mandibular cast and 25 mm of base on the maxillary cast. Measure up from the following locations:
  - The first molar cusp tip on each side
  - The canine cusp tip on each side
  - The incisor cusp tip on each side
- Use a model grinder to trim at the 25-mm and 30-mm circumferential markings, respectively, for the maxillary and mandibular casts.
- Remove all blebs from the occlusal surface of the dental casts.

Face-Bow Transfer: The Orientation of the Dental Casts (Maxilla and Mandible) on the Semi-Adjustable Articulator
(see Fig. 13-4, *A* through *F*)

- Secure the face-bow device to the semi-adjustable articulator. Adjust both the face-bow device and the upper arm of the articulator to be parallel to the floor and the counter lap.
- Secure the plastic base plate to the dental articulator. Place the maxillary cast on the bite-fork component of the secured face-bow device. Use white plaster to mount the maxillary cast to the base plate.
- Use the bite-fork support device to prevent the sagging of the maxillary cast during this process. Let the plaster initially set (≈15 min), and then remove the face-bow apparatus and the bite-fork support device.
- Turn the articulator upside down, and secure the mandibular cast to the maxillary unit with the use of the CR wax bite registration taken in the clinic setting. Further secure the occlusion in CR with two rubber bands to

compress the maxillary unit and mandibular cast together through the bite registration.
- Place the plastic base plate onto the dental articulator, and then use white plaster to mount the mandibular cast to the base plate. Let the plaster initially set (≈15 min).
- Cut the rubber bands used to secure the occlusion, and remove the wax bite.
- Remove the maxillary unit from the articulator. With the use of a model grinder, trim the maxillary cast, plaster base and the base plate all as one unit.
- Remove the mandibular unit from the articulator. With the use of a model grinder, trim the mandibular cast, the plaster base and the base plate all as one unit.

Placement of Reference Lines on the Maxillary and Mandibular Units (see Fig. 13-5, *A* through *E*)

- With the use of the Erickson Model Table, "score" two horizontal reference lines on the maxillary unit and then on the mandibular unit. Locate the horizontal reference lines on the maxillary and the mandibular units by doing the following:
  - Place the first horizontal line within the green stone.
  - Place the second horizontal line within the white plaster.
  - Ideally, there will be 15 mm to 20 mm of separation between these lines.
- With the use of a thick, black Sharpie pen, mark the "scored" horizontal circumferential reference lines on both the maxillary and mandibular units.
- With the use of a thick, black Sharpie pen, mark the vertical reference lines on both the maxillary and mandibular units. The vertical lines are located perpendicular to the horizontal lines and in the following places:
  - At the cusp tip of each canine
  - At the mesiobuccal groove of each first molar
  - Between the central incisors (i.e., at the dental midline)
  - Posterior at each tuberosity or retromolar area

Use of the Erickson Model Table to Define the Spatial Orientation of the Articulator-Mounted Maxillary Unit* (see Fig. 13-6)

With the use of a thin, black Sharpie pen, locate specific reference points from which measurements will be made. Place a dot at the following reference points:

- The cusp tip of each maxillary canine
- The mesiobuccal cusp tip of each maxillary first molar
- The midpoint of the incisal edge of each maxillary central incisor

Baseline vertical (maxillary) measurements: With the model block on its base, use the electronic caliper to measure the distance (in mm) at the following areas: (see Fig. 13-6 E and F)

- The incisal edge of each maxillary central incisor (#8, #9)
- The mesiobuccal cusp tip of each maxillary first molar (#3, #14)

Baseline horizontal (maxillary) measurements: With the model block on its end, use the electronic caliper to measure the distance (in mm) at the following area: (see Fig. 13-6D).

- The incisal edge of each maxillary central incisor (#8, #9)

Baseline dental midline (maxillary) measurements: With the model block on its side, use the electronic caliper to measure the distance (in mm) at the following areas: (see Fig. 13-6G)

- The dental midline with the left side of the cast down
- The dental midline with the right side of the cast down

Use of the Erickson Model Table to Define the Spatial Orientation of the Articulator-Mounted Mandibular Unit

Baseline horizontal (mandibular) measurement: With the model block on its end, use the electronic caliper to measure the distance (in mm) at the following area:

- The incisal edge of the mandibular central incisors (#24/#25)*

Separation of the Maxillary Cast from the Articulator Base (see Fig. 13-7, *A*)

- Remove the maxillary unit from the articulator. Separate the maxillary cast from the plaster base over a protective surface. You may first use the die saw to cut a groove in between the green stone and the plaster base. Insert a knife into this groove, and tap the knife with a hammer.

*The Erickson Model Table maxillary unit measurements that I find useful are outlined earlier in this chapter. Other measurements can be made in accordance with the clinician's preference.

*This is the only Erickson Model Table mandibular unit measurement that I find useful. Other measurements can be made in accordance with the clinician's preference.

Segmentation of the Maxilla
(see Fig. 13-7, *A*, *B*, and *C*)

Segmentation and Subsequent Reorientation of the Maxilla

- Use a die saw to segment the maxilla, as planned (i.e., two pieces versus three pieces).
- After the maxilla is segmented, align the segments over the mandibular arch into the preferred occlusion. Secure the segments back together with the use of hot glue from a glue gun.
  - Occlusal equilibration may be indicated to achieve the preferred occlusion (e.g., plunging palatal cusps on maxillary molars, bicuspid cusp reduction to level the posterior arch). If so, use a sharp plaster knife to complete adjustments on the occlusal surfaces of the maxillary and mandibular casts. Use a red Sharpie pen to mark the exact locations where enamel adjustments were made. The actual equilibration is carried out in the operating room.
  - When repositioning the maxillary segments into occlusion with the mandibular arch, it is essential to maintain the physiologic positioning of the interdental papilla and the contact points of adjacent teeth at all interdental osteotomy sites. If dental gaps are created or if cervical margins are not reasonably aligned, then periodontal sequelae are more likely.

Measurement of the Maxillary Arch Width Before and After Segmental Osteotomies

Transverse distance between maxillary molars (#3 to #14)
- Initial _____ (mm)
- After segmentation _____ (mm)

Transverse distance between maxillary canines (#6 to #11)
- Initial _____ (mm)
- After segmentation _____ (mm)

Use of the Erickson Model Table Measurements to Reorient the Maxillary Cast
(see Fig. 13-8, *A* through *F*)

- The repositioning of the maxilla on the articulator is meant to accurately match the desired surgical changes. These changes have been determined in accordance with the following: 1) the patient's clinical objectives (i.e., preferred facial aesthetics and improvements in function) 2) by taking into account any biologic skeletal, dental, or soft-tissue limitations and 3) the surgeon's clinical, dental, and radiographic analyses (see Chapter 12).
- After the key desired adjustments to the midface are reproduced on the maxillary unit, they are verified with use of the Erickson Model Table. The key millimeter and angular changes to be confirmed include the following:
  - Maxillary (midface) projection
    - Horizontal change at incisors
  - Maxillary incisor shown in repose and with smile
    - Vertical change at incisors
  - Maxillary plane change (pitch orientation) and cant correction (roll orientation), which are controlled by the following:
    - Vertical change at incisors
    - Vertical change at first molars
  - Maxillary midline position (yaw orientation)
    - Dental midline change (right side down)
    - Dental midline change (left side down)
  - Considerations of lateral tuberosity position (yaw orientation)
    - Analysis of lateral shift (change) at posterior maxilla (tuberosity region)
- Soft wax or clay is used in a tripod fashion to facilitate the initial placement of the maxillary cast back onto the plaster base on the articulator in the preferred position. It is generally necessary to trim the stone or plaster before repositioning. Fine tune the maxilla into the preferred position with the use of the Erickson Model Table (i.e., via horizontal, vertical, and transverse measurements). After these measurements are confirmed, fully secure the preferred maxillary position to the plaster base with hot glue from a glue gun.
- When repositioning the maxilla into the preferred position, take into consideration the yaw orientation. Control the yaw orientation to avoid unwanted asymmetric shifts, which would be visually noticeable in the cheeks of the midface and at the mandibular angles (see Chapter 12).

Intermediate Splint Construction for the Positioning of the Maxilla During Operation (see Fig. 13-9, *A* through *E*)

- With the maxilla secured in the new preferred position but without any changes yet made to the baseline mandibular position, the intermediate (occlusion) splint is constructed.
- Apply a thin coat of Vaseline to the maxillary and mandibular occlusal surfaces with a toothbrush.
- Use pink acrylic liquid and standard acrylic powder. Mix these until the mass does not slump. Apply Vaseline to your hands, and roll the mass into a log shape. Adapt the mass to the maxillary occlusal surface, and close the articulator until the vertical pin touches. This will result in an imprint of the mandible occlusal surfaces on the opposite side.
- Maintain the acrylic just below the level of the base of the maxillary orthodontic brackets and just above the base of the mandibular orthodontic brackets. Use sharp

NOTE: When making the intermediate splint, maintain the vertical pin of the articulator in a neutral position, unless significant inferior positioning (i.e., lengthening) of the maxilla is planned. If so, there are two options: either take the initial CR bite (in the clinic setting) with an increased freeway space (this is equivalent to the clockwise rotation of the mandible while the condyles remain seated in the fossa) or lengthen the vertical pin on the articulator (this is also equivalent to the clockwise rotation of the mandible while the condyles remain seated in the fossa) before making the intermediate splint. Either approach can be used without error as long as the mandibular opening is limited to temporomandibular joint rotational movement. If temporomandibular joint transitional movement occurs, then the splint will no longer reflect the patient's CR bite. If the clinician is uncomfortable with this approach, then a mandible-first approach to analytic model planning should be used (see Chapter 14).

scissors to remove gross excess. This will prevent "undercuts" of acrylic on the brackets.
- Continuously open and close the articulator until the acrylic sets (≈10 min). Maintain the vertical pin in a neutral position and fully closed. This will ensure that no "undercuts" remain.

Trimming of Hardened Acrylic Intermediate Splint (see Fig. 13-9, *F* and *G*)

- Remove excess buccal (labial) acrylic when looking at the model from a bird's-eye view. Use a pencil to mark a line parallel to and just outside of the maxillary orthodontic brackets. Draw a similar line outside of the mandibular brackets. With a lathe and a circular white stone or an acrylic bur, trim excess acrylic, as marked.
- Prevent lingual ramping by removing excess acrylic in the region of the mandibular anterior teeth. This limits interferences that tend to occur as a result of the arc of rotation of the mandible during mouth opening and closing.
- When viewing the splint from the side, mark with a pencil any areas that require further acrylic removal (e.g., just below the base of the maxillary orthodontic brackets, just above the base of the mandibular orthodontic brackets). With a lathe and a circular white stone or an acrylic bur, trim excess acrylic, as marked.

NOTE: If greater strength is needed for the intermediate splint (see Fig. 13-10, *F*), then reinforce with a palatal wire (e.g., use a piece of a heavy paper clip) and additional acrylic.

- If segmental osteotomies are planned, maintain at least 3 mm to 4 mm of lingual acrylic behind the incisors to prevent splint breakage or torque, which may otherwise occur in the operating room.

Reorientation of the Mandibular Cast to Register the Final Occlusion (see Fig. 13-10, *A* and *B*)

- Separate the mandibular cast from the plaster base (as was done for the maxillary cast).
- Articulate the mandibular cast with the maxillary unit in the desired final occlusion, and secure the occlusion with hot glue.
- With the vertical articulator pin remaining in a neutral position, secure the mandibular cast back to plaster base. This may require the removal of interferences in the plaster base or the addition of material (e.g., plaster, hot glue).
- Remove the glue that was used to secure the occlusion, and confirm the accuracy of the final occlusion.

Final Splint Construction for the Positioning of the Mandible During Operation (see Fig. 13-10, *C* through *F*)

- Reapply Vaseline to the maxillary and mandibular occlusal surfaces of the teeth with a toothbrush.
- Mix clear acrylic liquid and standard powder. Mix these until the slumping stops. Vaseline your hands, roll the acrylic into a log shape, and then adapt and readapt it as described for intermediate splint construction.
- Trim the final occlusion splint as described for the intermediate splint. Smooth the lingual edges for patient comfort.
- If segmental osteotomies are planned, maintain at least 3 mm to 4 mm of lingual acrylic behind the incisors to prevent splint breakage or torque, which may otherwise occur in the operating room.

NOTE: If greater strength is needed for the final splint (see Fig. 13-10, *F*), then reinforce with a palatal wire (e.g., use a piece of a heavy paper clip) and additional acrylic.

Finishing of the Prefabricated Acrylic Splints (see Fig. 13-10, *G* and *H*, and Fig. 13-11, *A* and *B*)

- Place each splint in between the maxillary and mandibular units to determine the ideal location and direction of each interdental hole placement. Mark these placements with a pencil.

- Drill holes that are 1 mm in diameter in both the intermediate and final splints at each interdental location for the ease of passage of the wires through the splint. For ease of wire passage, the holes are located below the maxillary orthodontic arch wire.
- Polish the splints on the lathe with a cloth buffing wheel using pumice (i.e., coarse, medium, and then fine) and Acrilustre (Vogel Paint and Wax Co. Inc., 1020 Albany Place, SE; Orange City, Iowa)

Accuracy of the Described Analytic Model Planning Technique: Review of Study

A research study was carried out to assess the accuracy of analytic model planning to achieve the desired maxillary advancement during bimaxillary orthognathic surgery.[54]

Material and Methods

A consecutive series of patients (n = 20) who underwent at a minimum Le Fort I osteotomy with advancement and sagittal ramus osteotomies of the mandible for the correction of dentofacial jaw deformities were included in the study group. The sample consisted of female (n = 9) and male (n = 11) with a mean age of 21 years (range, 14 to 45 years). All study subjects underwent the following: 1) preoperative and 5-week postoperative lateral cephalometric radiographs of acceptable quality with a metric reference frame for analysis; 2) consistent presurgical facial analysis by the surgeon, including millimeter decisions regarding planned horizontal and vertical repositioning and three dimensional reorientation (i.e., pitch, roll, and yaw) of the maxilla; 3) consistent analytic model planning as described in this chapter 4) the construction of intermediate and final splints; 5) the use of the prefabricated intermediate splint to establish the maxillary positioning after Le Fort I osteotomy and before plate and screw fixation, and 6) the use of consistent intraoperative landmarks (i.e., the distance between the medial canthus and the maxillary central incisor measured in millimeters with the use of calipers) to confirm vertical orientation.

The determination of the preferred surgical reorientation of the jaws was based on a combination of the direct visual examination of the patient in the clinic setting, the analysis of the lateral cephalometric radiograph, and the analysis of the profile facial photograph taken in the NHP during the presurgical office visit. The extent of preferred maxillary horizontal advancement in millimeters was ultimately assessed by the surgeon with the patient in the NHP during the direct visual examination, with all gathered data taken into account. The fabrication of an intermediate splint to capture the preferred maxillary horizontal and other vector movements (i.e., pitch, yaw, and roll) with the use of consistent analytic model surgery planning methods was accomplished.

Radiographic Analysis

For each study patient, a presurgical standard cephalometric radiograph was obtained for later analysis. At 5 weeks after surgery, a similar standard cephalometric radiograph was also taken. This was timed to coincide with initial bone healing and the removal of the surgical splint.

Four landmark points (i.e., the sella, the nasion, the porion, and the orbitale) that remained unchanged after Le Fort I advancement were used for this analysis. These points were used to create a consistent reference line from which linear measurements (e.g., a change in the horizontal position of the maxillary incisors) could be made and compared before and after maxillary advancement. To confirm the consistency of the four designated points in the sequential radiographs, a reference angle between SN and FH was verified to remain within 0.5 degrees.

On each cephalometric radiograph, a perpendicular reference line passing through the sella, called the *sella perpendicular (S⊥)*, was then dropped. From S⊥, a direct linear measurement was made parallel to the Frankfort horizontal *(FH)* plane and extended to the maxillary incisal edge *(U1)* (Fig. 13-14).

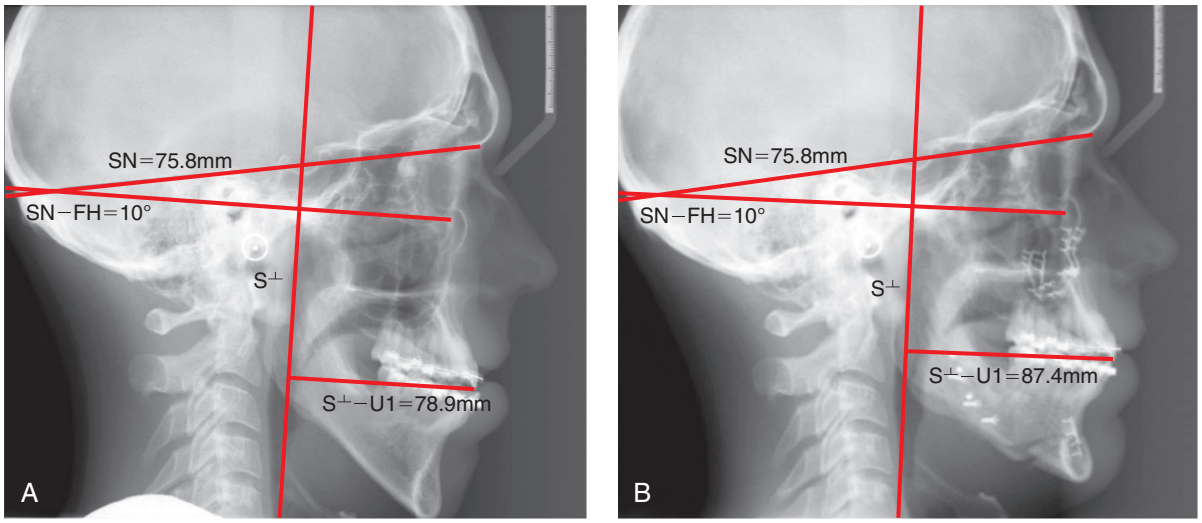
To accurately access the horizontal advancement of the maxillary incisors accomplished during the operation and maintained at 5 weeks, the distance in millimeters from S ⊥ to U1 was measured on both the preoperative and the 5-week postoperative lateral cephalogram. The measurements were then adjusted with the use of a metric reference frame to correct for magnification. Any difference in length of these two data points corresponds with variations in the preoperative and postoperative (i.e., at 5 weeks after surgery) horizontal positions of the maxillary central incisors.

Comparisons between the planned and actually achieved (at 5 weeks after surgery) horizontal positions of the maxillary incisors were made with the paired *t*-test. Statistical significance was set at $P < .05$. Associations between the planned and postsurgical results were investigated with Pearson's correlation.

Results

The collected data for all study patients are presented in Table 13-1. In all cases, the surgically achieved and maintained (i.e., at 5 week postoperatively) horizontal advancement measured at the maxillary incisors was within 1.0 mm of what was planned. There was a strong correlation between the two data sets (R = 0.96) (Fig. 13-15). With the use of the absolute measurement values, the mean difference between the planned and actual 5-week postsurgical horizontal advancement of the maxilla was found to be 0.6 mm (range, 0.2 to 1.0 mm). According to the paired *t*-test, this mean difference was not considered to be statistically significant ($P > .05$).

The distribution of the absolute difference in millimeters between the planned, actually achieved, and then



• **Figure 13-14** Example of lateral cephalometric radiographs and measurements taken in study patients showing maxillary advancement in millimeters. • **Figure 13-15** Data from study patients undergoing Le Fort I advancement. The correlation between the planned and actual advancement at the maxillary incisors is shown (R = correlation coefficient). *From Park N, Posnick JC: Accuracy of analytic model planning in bimaxillary surgery,* Int J Oral Maxillofac Surg. *42:807-814, 2013.*

maintained maxillary advancement is presented in Table 13-2. For the majority of patients, the difference fell within 0.4 to 0.8 mm. In 17 of the 20 patients (85%), there was a small undercorrection; in 3 of the 20 patients (15%) there was a slight overcorrection.

The results of this study confirm that the described method of analytic model planning in orthognathic surgery is reliable in achieving the planned level of maxillary advancement in bimaxillary procedures.

Conclusions

Orthognathic surgery requires a thorough head and neck examination and precise preoperative dental, radiographic, and aesthetic preparation. Although clinical decision making regarding the preferred spatial reorientation of the jaws to achieve improved function and enhanced facial aesthetics remains both an art and a science, the technical aspects of model planning should be precise and consistent. Current methods of analytic model planning and the use of prefabricated splints represent the standard of care for bimaxillary and segmental maxillary osteotomies.

TABLE 13-1 **Maxillary Incisor Vertical Change, Plane Change, and Incisor Horizontal Change: Planned and Actual**

- Conclusions

Unlike most surgical procedures, orthognathic surgery involves not just thorough medical assessment but also precise preoperative dental, radiographic, and facial aesthetic planning. The surgeon also carries out a detailed face-to-face examination of the patient to determine variations from normal.

Immediate presurgical records include current dental impressions of the maxillary and mandibular arches; accurate bite registration in centric relation (CR); a face-bow registration; and the recording of specific facial measurements, including deviations from normal. The dental models are placed on a semi-adjustable articulator for further analysis, and they are then used to complete analytic model planning.[1,2,10,13,15,39,40] Acrylic splints are fabricated and used intraoperatively to further ensure the reliable execution of the predetermined reorientation of the maxilla and mandible to achieve facial aesthetic and functional objectives.

Although the making of clinical decisions about the preferred aesthetic repositioning of the jaws remains both an art and a science (see Chapter 12), the technical aspects of model planning should be precise and consistent. Analytic model planning and the use of prefabricated splints continue to represent the standard of care for bimaxillary and segmental maxillary osteotomies.[6,14,17,52]

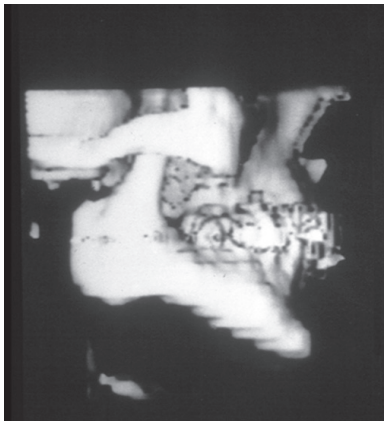
Despite the benefits of this time-honored model planning approach, there is the potential for the introduction of error. For example, if an inaccurate CR bite registration is obtained from the patient preoperatively. The surgeon's ability to obtain an accurate and reproducible bite registration in CR during the immediate presurgical clinical examination, during the occlusion of the dental models on the articulator in the laboratory, and when using the splints in the operating room is essential to avoid errors when *standard analytic model planning* is employed.[5,12,13,17-28,32,33,35,36,53]

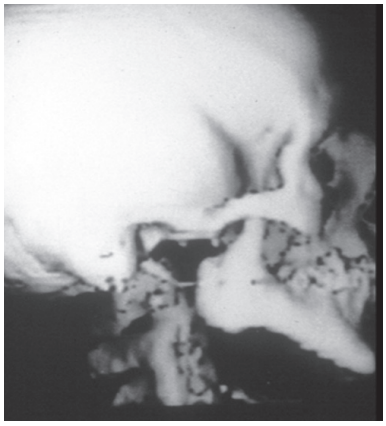
There are specific clinical settings in which the obtaining of an accurate and reliable CR can be problematic.[8,11,34,37,39,52] Examples include the following individuals: 1) those who are missing a condyle after tumor resection 2) those with severe atrophy of the condyle after trauma and 3) those with specific syndromes in which the condyle-ascending ramus is aplastic (e.g., Treacher Collins syndrome, or hemifacial microsomia with Kaban type IIB or III malformation; see Chapters 27 and 28) (Fig. 14-1) For those patients with an unreliable CR, a *"mandible-first" approach to analytic model planning* is required.

Controversies Surrounding Centric Relation

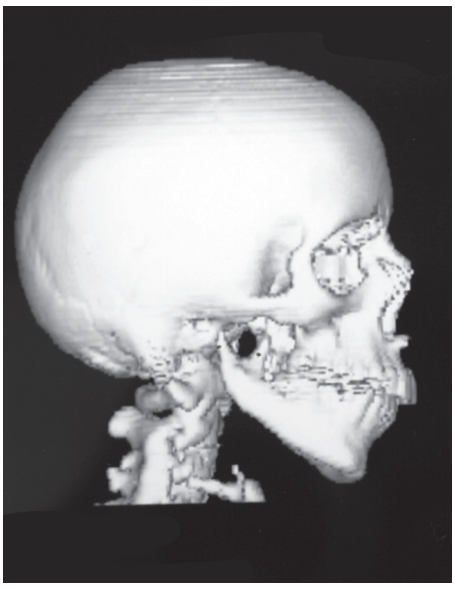
Definition of Centric Relation

The definition of CR remains somewhat controversial, and it is frequently misstated.[46-49] In 1987, the definition of CR underwent a change in terminology from being considered a mandibular position in which the condyles are seated in the most "posterior superior" position to one in which the condyles are placed in the most "superior anterior" position in the glenoid fossa.[45,46] For analytic model planning in





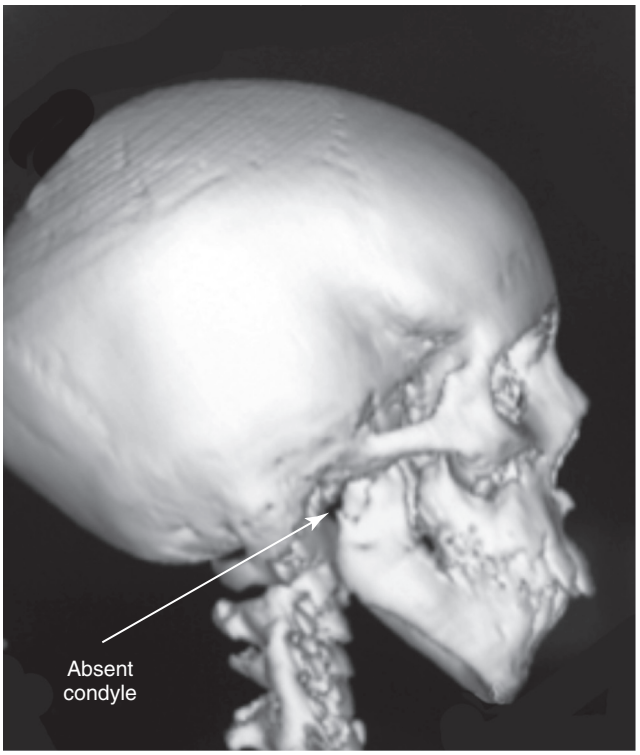
Kaban type II B



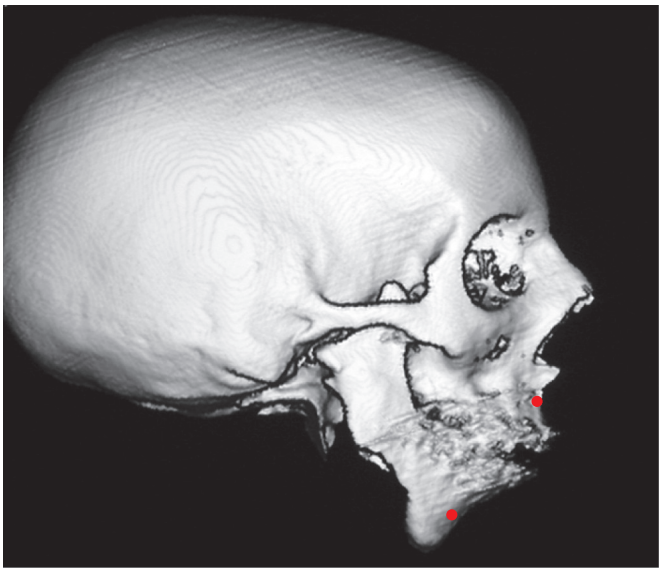
Kaban type II B

• **Figure 14-1** There are specific clinical settings in which obtaining an accurate and reliable centric relation (CR) can be problematic. Examples include individuals with atrophy of a condylar head (e.g., after a displaced condyle fracture) or those with specific syndromes in which aplasia of the glenoid fossa and condyle of the ascending ramus is extensive (e.g., Treacher Collins syndrome, hemifacial microsomia [HFM] with Kaban type IIB or III mandibular malformations). In addition, there are unique circumstances in which patients undergo bimaxillary procedures that require posterior maxillary lengthening to the extent that clockwise rotation of the mandible would result in a translational movement of the condyles in the glenoid fossa. In these cases, a mandible-first approach to analytic model planning is indicated. Several clinical examples are shown. **A,** A 16-year-old boy who had sustained a fracture of the right condyle of the mandible earlier during his childhood presented as a teenager with facial asymmetry. Complete atrophy of the right condyle had occurred, with a loss of posterior facial height. For this reason, a stable CR bite registration was not possible. Facial and computed tomography (CT) scan views are shown to confirm these facts. **B,** A 14-year-old girl with right-sided HFM and a Kaban type IIB condyle and ascending ramus malformation is shown. Because of these conditions, obtaining a consistent CR bite registration was not possible. Facial and CT scan views confirm these findings.

Continued



Kaban type II B



Kaban type II A

• **Figure 14-1, cont'd C,** An 11 year-old-boy who was born with right-sided HFM and a Kaban type IIB condyle and ascending ramus malformation is shown. Because of these conditions, obtaining a consistent CR bite registration was not possible. Facial and CT scan views confirm these findings. **D,** A teenage girl with a bilateral form of HFM and a Kaban type IIA condyle and ascending ramus malformation is shown. Although a stable CR bite registration could be obtained, the correction of the bimaxillary deformity requires significant counterclockwise rotation of the maxilla, including the lengthening of the posterior facial height of the maxilla. The use of standard maxilla-first analytic model planning would require clockwise rotation of the mandible to place the intermediate splint to the extent that translational movement of the condyles in the glenoid fossa would occur. For this reason, a mandible-first approach is required. Facial and CT scan views confirm these findings.

preparation for orthognathic surgery, defining the exact position of each condylar head during mandibular protrusion and lateral excursions is not critical. However, it is essential to locate a mandibular position that is reproducible with the teeth in occlusion. This must be obtained without the assistance of the patient (i.e., with fully relaxed masticatory muscles), and it needs to be reliably accomplished both preoperatively and intraoperatively. This position must also be transferable to the articulator in the laboratory for model planning to be accomplished accurately. An erroneous and inconsistent recording of CR will lead to the malpositioning of the maxilla or mandible during surgery.

A survey study conducted by Truitt and colleagues confirmed that 98% of oral and maxillofacial surgeons define CR as the most posterior superior seating of the condyle in the fossa.[51] Interestingly, a majority of the orthodontists surveyed agree with the surgeons' definition of CR, but there was less consistency.[22,41] According to the survey, surgeons and orthodontists do agree that, in preparation for orthognathic surgery, analytic model planning requires that casts of the teeth be mounted in CR on a semi-adjustable articulator.

Capturing Centric Relation

Hellsing and McWilliam used a subtraction technique to assess the repeatability of CR that is recorded with a *one-handed push-back technique*.[21] They found that, with the use of this technique, the mandibular condyles can be seated in a reproducible position and thus be well suited for the registration of CR. Campos and colleagues compared the *swallowing technique* with the *chin-point guidance technique* when the patient was in both upright and supine body positions.[3,5,9,15,21] Both techniques were found to establish physiologic CR in a reproducible manner. Interestingly, when the chin-point guidance method was used, the work of these authors suggested that reliability was greater with the patient in the upright, seated position as compared with the supine position.

Simon and Nicholls compared the *chin-point guidance, chin-point guidance with ramus support,* and *bimanual manipulation* techniques.[43] They found that there were no significant differences in the range of mandibular positions that were observed. Interestingly, their study patients did not include individuals with jaw deformities. It is known that patients with specific patterns of jaw deformity (e.g., Class II retrognathism) are more likely to involuntarily posture the mandible forward during the swallowing technique.

When a reliable CR can be obtained, we find the *chin-point guidance technique*—when used both preoperatively and intraoperatively by the same clinician—to be both reliable and convenient for the orthognathic surgery patient. This is the method that has been adopted by this author, and it has been used successfully for orthognathic patients that have a reliable CR. By using one hand to apply pressure to the subject's chin and the other hand to apply opposing pressure to the occiput, the clinician is able to apply posterior and superior "vectored" force to the anterior mandible. This will seat the condyles in a superior-anterior location within each glenoid fossa (i.e., CR).

Unstable (Unreliable) Centric Relation

Alternative methods to the standard analytic model planning approach to bimaxillary orthognathic surgery have been described in an attempt to improve the accuracy and predictability of outcomes.[8,11,34,37,50,52] Recently, surgeons have also begun looking to computer-aided design and computer-aided modeling software to assist with the planning and implementation of orthognathic procedures (see Chapter 13).[3,4,7,14,16,18,19,20,29,30,31,38,42,44,54,55,56]

The subset of patients in which obtaining an accurate CR is not feasible are well suited for a *"mandible-first" approach*. Common clinical examples of these patients include the following: 1) those with specific congenital anomalies (e.g., hemifacial microsomia with Kaban Type IIB or III malformations) (Fig. 14-2 and 14-3) 2) those with specific types of trauma (e.g., after condylar fracture with resorption or after ankylosis release with condylar resection) 3) those with specific pathology (e.g., after condylar resection for tumor) and 4) those with the inability to cooperate in the office setting (e.g., those with neuropsychiatric disorders that involve uncontrolled masticatory muscle spasticity).

A *mandible-first approach to analytic model planning* is also indicated in unique clinical circumstances in which significant posterior maxillary lengthening is planned to the extent that the clockwise rotation of the mandible will require the translational movement of the condyles in the glenoid fossa during the use of the intermediate splint (Fig. 14-4). Fortunately, these cases are not common; very few patients require the actual lengthening of the posterior maxillary height. Furthermore, those who do generally either require the closure of baseline posterior open bites (i.e., cases that involve the failure of the posterior dentition to erupt) or are undergoing simultaneous advancement. For example, the advantage of the counterclockwise rotation of the maxillary and mandibular planes (i.e., pitch orientation) is frequently seen in the clinical setting of a long face growth pattern. This counter clockwise rotation is generally accomplished via the differential intrusion of the maxilla (i.e., anterior more so than posterior). This does not require the lengthening of the posterior maxillary height or the overall posterior facial height (see Chapter 21).

Mandible-First Analytic Model Planning Technique

We prefer to use the *mandible-first analytic model planning technique,* in only specific clinical situations (see Fig. 14-1 through 14-4).[8,11,34,37,39,52] However, whichever method of model planning is used, all orthognathic patients require a thorough clinical history and physical examination. A

maxillofacial and focused dental assessment is also completed with particular emphasis on the accurate documentation of the following: 1) any maxillary occlusal cant (i.e., role orientation) 2) the maxillary and mandibular dental midline positions relative to the facial midline (i.e., yaw orientation) 3) any disproportions in vertical facial height 4) any disproportions in the horizontal projection of each jaw and 5) any advantage to the alteration of the maxillary or mandibular planes (i.e., pitch orientation); (see Chapter 12).

The basic technical aspects of *mandible-first analytic model planning* include the following:

1. To register the bite in a patient with a unilateral "free-floating" condyle–glenoid fossa relationship (e.g., Kaban type IIB or III hemifacial microsomia, the absence of the condyle after tumor resection or trauma), the mandible is manipulated with the "normal" condyle placed reliably in the terminal hinge position and with the "abnormal" (i.e., contralateral) condyle seated in its most posterior-superior position. This will demonstrate the maximum mandibular deformity. A wax bite registration is taken in this position.
2. A face-bow registration is obtained. Care is taken to accurately reproduce the patient's existing maxillary plane (pitch orientation), cant (role orientation), and midline (yaw orientation) in relationship to the upper face. If the cranial base and the external auditory canals have essentially normal morphology, this is accomplished in a traditional fashion with the use of the standard face-bow technique, which involves placing an earpiece in each ear canal. If the patient's ear canals are abnormally formed or positioned (e.g., in a patient with hemifacial microsomia with external auditory canal atresia), adjustments are made by using references to the parallelism of the floor and the morphology of the orbits. When doing so, the earpieces maybe placed against the patient's cheek skin (rather than in the dysmorphic or absent external auditory canal). The patient's head and neck are positioned by the operator in the natural head position for the face-bow registration (see Chapters 12 and 13).
3. Two maxillary and one mandibular alginate impressions are taken. The three dental impressions are poured in green die stone. The first maxillary cast is mounted onto the articulator in the standard fashion with white plaster and the use of the face-bow registration for orientation. The wax bite registration is then used to articulate the maxillary and mandibular casts to each other. The mandibular cast is then mounted on the articulator in the standard fashion, also with the use of white plaster (see Chapter 13).
4. The first maxillary mounting is removed, and the second maxillary cast is mounted. This is accomplished with the use of the original bite registration against the already mounted mandibular cast. Vertical and horizontal reference lines are created on each maxillary and mandibular unit (see Chapter 13). The Erickson Model Table is used to make baseline millimeter reference measurements on both maxillary units and the mandibular unit (see Chapter 13).
5. The original maxillary cast is then separated from its plaster base and three-dimensionally repositioned and reoriented according to the treatment plan. The Erickson Model Table is used to confirm the correct reorientation. If segmentation is required, it is completed before the reorientation of the maxilla to the plaster base (see Chapter 13). The reorientation of the maxilla takes into account the preferred horizontal, vertical, transverse (segmental) midline (yaw), cant (roll), and plane (pitch), needs (see Chapter 12). The maxillary cast is then secured to the plaster base with hot glue in the planned treatment position on the articulator (see Chapter 13).
6. The mandibular cast is then separated from its base and repositioned into the preferred final occlusion to the reoriented maxillary unit with the use of hot glue. The mandibular cast is remounted to its plaster base in the new position on the articulator with hot glue. The occlusion is released (i.e., the glue that secured the occlusion is removed), and a "maxillary-positioning" splint is fabricated with acrylic (see Chapter 13).
7. Next, the repositioned (reoriented) maxillary unit is removed from the articulator and replaced with the "uncut" second maxillary unit. This indicates the new mandibular location and the "unoperated" maxillary position. The "mandibular-positioning" splint is then fabricated with acrylic.

Technical Aspects of Executing the Mandible-First Approach During Orthognathic Surgery

Consider as an example an individual with hemifacial microsomia and a Kaban type IIB mandibular malformation ((Fig. 14-2 and 14-3). When using the mandible-first approach, the "normal" side of the ramus of the mandible is split sagittally in the usual way (i.e. sagittal ramus osteotomy of mandible). The distal mandible is then placed into its treatment-planned final position with the use of the prefabricated "mandibular-positioning" splint, and intermaxillary fixation (IMF) is established. To fully mobilize the distal mandible and secure it into the new occlusion, it may be necessary to 1) complete an ipsilateral coronoidectomy, 2) excise portions of the rudimentary (ipsilateral) mandible, or 3) both.

After the distal mandible is in the splint and secured with IMF, the proximal segment on the "normal" side is seated into the terminal hinge position. Rigid internal fixation (e.g., bicortical screws) is then established across the ramus osteotomy site (see Chapter 15).

The deficient portion of the ipsilateral mandible is constructed with the use of a bone graft (e.g., a costochondral graft). The neocondyle is seated in the glenoid fossa. Once in place, fixation of the graft is achieved to the distal

mandible with an extended titanium plate and screws. The IMF is released, and the occlusion is confirmed to be accurate and reproducible into the splint.

The "mandibular-positioning" splint is removed, and the maxillary (Le Fort I) osteotomy is performed. After downfracture and disimpaction (including segmentation, if indicated), the "maxillary-positioning" splint is used to achieve the treatment-planned maxillary reorientation. Plate and screw fixation is secured across the maxillary osteotomy sites in the usual manor (see Chapter 15). The IMF is released, and an accurate and reproducible occlusion is confirmed. The splint is either removed or left in place, depending on the patient's clinical healing needs.

Mandible-First Analytic Model Planning: Step-by-Step Approach

1. Obtain a wax bite registration with the normal (unaffected) condyle seated in the terminal hinge position and with the abnormal (hypoplastic) condyle positioned as posterior and superiorly against the skull base as possible.
2. Use the face-bow device to register the relationships of the maxilla, glenoid fossa, and the skull base while the patient is in the natural head position (NHP). Use a modified technique if ear canals and the orbital symmetry are abnormal.
3. Take alginate impressions (two maxillary, one mandibular).
4. Pour alginate impressions in green die stone with a 25- to 30-mm base.
5. Mount the first maxillary cast onto the articulator base plate with the use of white plaster and the face-bow recording.
6. Turn the articulator upside down and place the mandibular cast onto the already mounted maxillary unit with the use of the wax bite registration. Mount the mandible cast onto the articulator base plate with white plaster.
7. Remove the mounted maxillary unit, and mount the second maxillary cast onto the articulator base plate with white plaster and the use of the same CR bite registration.
8. Mark vertical and horizontal reference lines on all three units, and take baseline measurements on the first maxillary unit with the use of the Erickson Model Table.
9. Perform model surgery on the first maxillary cast (including segmentation, if indicated). Place the maxilla in its treatment-planned location. Use the Erickson Model Table to confirm correct positioning. Secure the maxillary cast to the articulator (in its new location) with hot glue.
10. Separate the mandibular cast from the base. Secure the mandibular cast with hot glue into the optimal final occlusion against the repositioned maxillary cast. Secure the mandibular cast with hot glue or plaster back onto the base plate of the articulator.
11. Release the occlusion (i.e., remove the glue), and fabricate the "maxillary-positioning" splint in the standard fashion with the use of acrylic.
12. Remove the first maxillary (cut) unit, which is currently on the articulator, and place the second (uncut) maxillary unit.
13. Fabricate the "mandibular-positioning" splint in the standard fashion with the use of acrylic. This will be with the final (cut) mandibular unit and initial (uncut) maxillary unit.

Case Presentations

• CASE 14-1

Hemifacial Microsomia

A child was born with right-sided hemifacial microsomia that was manifested by mild hypoplasia of the affected soft tissues, paresis of the temporal branch of the facial nerve, a degree of zygoma and orbital hypoplasia, and a Kaban type IIB mandibular malformation (Fig. 14-2). The right external ear was displaced but had acceptable formation. She underwent orthodontic alignment during early adolescence, and she was referred to this surgeon when she was 14 years old. At age 16, after the completion of her orthodontic preparation, she underwent a maxillary Le Fort I osteotomy with three-dimensional repositioning (cant correction, occlusal plane adjustment, midline correction, and vertical and horizontal adjustments); sagittal split osteotomy of the left ramus; reconstruction of the right condyle and ascending ramus with an autogenous costochondral graft; osseous genioplasty (horizontal advancement and asymmetry correction); and intranasal procedures (septoplasty, and inferior turbinate reduction).

• **Figure 14-2** A 14-year-old girl who was born with right-sided hemifacial microsomia and a Kaban type IIB condyle and ascending ramus malformation was followed longitudinally without treatment intervention until skeletal maturity. Facial asymmetry demonstrated no progression during this time frame. During the adult dentition and with orthodontic dental decompensation complete, she underwent single-stage reconstruction that included a maxillary Le Fort I osteotomy a left-sided sagittal split ramus osteotomy; right mandible reconstruction with costochondral graft septoplasty and inferior turbinate reduction. Improvements in the inferior border of mandible symmetry after surgery have been documented. However, significant soft-tissue asymmetry in the pre-auricular cheek region remains. Fat grafting is an option to consider. **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

• CASE 14-2

Hemifacial Microsomia

A child was born with right-sided hemifacial microsomia, which was manifested by moderate hypoplasia of the right-sided soft tissues, displacement and deformity of the external ear, anomalous external auditory canals, and a Kaban type IIB mandibular malformation (Fig. 14-3). Left-sided macrosomia repair was carried out during childhood. During the late mixed dentition, the patient was referred to this surgeon for evaluation (see Fig. 28-15). After orthodontic preparation, he underwent a maxillary Le Fort I osteotomy in two segments with three-dimensional repositioning (horizontal advancement, vertical shortening, transverse expansion, dental midline shift, occlusal plane change, and cant correction); sagittal split osteotomy of the left ramus; reconstruction of the right condyle and ascending ramus of the mandible with an autogenous costochondral graft; osseous genioplasty (advancement and asymmetry correction); an intranasal procedure (septoplasty and inferior turbinate reduction); and bilateral otoplasty (set-back).

• **Figure 14-3** A child who was born with hemifacial microsomia of the right side of face and a type IIB condyle and ascending ramus malformation was followed longitudinally without treatment intervention until skeletal maturity (see Fig. 28-15). Facial asymmetry demonstrated no progression during this time frame. During the adult dentition and with orthodontic dental decompensation complete, the patient underwent single-stage reconstruction that included a maxillary Le Fort I osteotomy a left-sided sagittal split ramus osteotomy; right mandibular reconstruction with costochondral graft osseous genioplasty septoplasty, inferior turbinate reduction, and bilateral otoplasty (ear set-back). **A,** Facial views in repose before and after reconstruction. **B,** Facial views with smile before and after reconstruction.

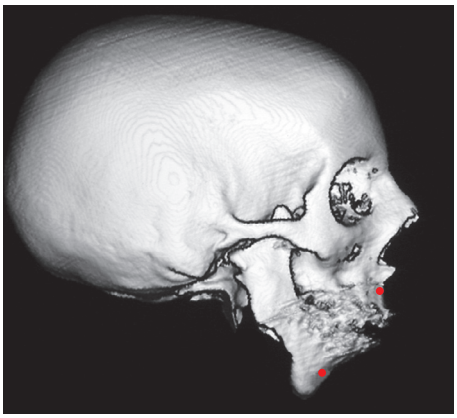
• CASE 14-3

Hemifacial Microsomia

A child was born with an asymmetric bilateral form of hemifacial microsomia that was manifested by moderate hypoplasia of the affected soft tissues (including the muscles of mastication), bilateral microtia, atresia of the external auditory canals, and mild bilateral hypoplasia of the zygomas and the orbits. Bilateral asymmetric Kaban type IIA mandible malformations were present (Fig. 14-4). The patient's previous surgeries included multiple external ear reconstructive procedures by another surgeon, including the placement of autogenous costochondral grafts. She also underwent an attempt to open the left external auditory canal by another surgeon, but this was aborted after facial nerve concerns. Mandibular reconstruction was attempted twice (when the patient was 7 and 11 years old) by another surgeon with the use of distraction osteogenesis techniques, but this had limited results. The previous procedures created intraoral and facial scarring, and a 15-mm anterior open-bite malocclusion remained.

At 14 years old, the patient was referred to this surgeon for evaluation (see Fig. 28-16). After additional orthodontic preparation, she underwent maxillary Le Fort I osteotomy; bilateral coronoidectomies; bilateral sagittal ramus osteotomies (with autogenous iliac corticocancellous interpositional bone grafts); osseous genioplasty (advancement and shortening); and intranasal procedures (septoplasty and inferior turbinate reduction). The described mandible-first analytic model planning technique was used.

Unfavorable A-pt. to B-pt. relationship



Distraction osteogenesis effects on mandibular ramus/angle

• **Figure 14-4** A girl was born with a bilateral form of hemifacial microsomia and Kaban type IIA condyle and ascending ramus malformations (see Fig. 28-16). When she was 7 and 11 years old (and at another institution), she underwent bilateral distraction osteogenisis of the mandible. The procedures were unsuccessful. She also underwent bilateral external ear reconstruction with a suboptimal result. The patient wore external hearing aids. Earlier orthodontic treatment was carried out (at another institution) including four bicuspid extractions. After presenting to this surgeon when she was 15 years old, the patient underwent reconstruction that included a Le Fort I osteotomy bilateral ramus osteotomies with interpositional grafting; osseous genioplasty; septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Profile facial and computed tomography scan views at the time of referral to this surgeon. **B,** Frontal views with smile before and after reconstruction. *Continued*

Conclusions

During model planning in preparation for orthognathic surgery, the introduction of error can occur when obtaining the bite registration in the clinical setting. There are specific clinical settings in which the obtaining of an accurate and reliable bite registration can be problematic. For these patients, a *mandible-first approach to analytic model planning* for the achievement of accurate and reliable results is required.

Sequencing of Orthognathic Procedures: Step-by-Step Approach

JEFFREY C. POSNICK, DMD, MD

- Description and Sequencing of Orthognathic and Other Frequent Simultaneous Procedures: Step-by-Step Approach
- Conclusions

Maxillofacial surgeons and orthodontists are the primary clinicians who care for individuals who present with jaw deformities, malocclusions, and the associated facial dysmorphologies. When an orthognathic approach is indicated, there are a limited number of basic surgical techniques that are used to facilitate the three-dimensional repositioning of the skeletal units (i.e., the maxilla, the mandible, and the chin region) to achieve desired improvements in head and neck function and to enhance facial aesthetics. By and large, these options include the Le Fort I (Type) osteotomy, with or without segmentation of the down-fractured maxilla; sagittal split ramus osteotomies of the mandible; and an oblique osteotomy of the chin. Each of these three basic osteotomies and its associated fixation techniques has evolved gradually to its current usage (see Chapter 2).[1-6]

This chapter provides the surgeon with a step-by-step technical description for the safe execution of Le Fort I osteotomy of the maxilla, sagittal split ramus osteotomies of the mandible, osseous genioplasty, and other frequent simultaneously performed procedures (e.g., septoplasty, reduction of inferior turbinates, recontouring of the nasal floor, removal of wisdom teeth, neck region soft-tissue rejuvenation) as I routinely carry them out (Video 6 and 7). The approach is described as it is typically executed for the patient who is undergoing all of these procedures simultaneously. An individual's unique anatomy and clinical presentation may require variations in surgical approaches and sequencing of treatment.

Description and Sequencing of Orthognathic and Other Frequent Simultaneous Procedures: Step-by-Step Approach

Preparation and Draping

Step 1. The patient is placed supine on the operating room table with the head in a Mayfield (horseshoe) headrest in the neutral neck position.

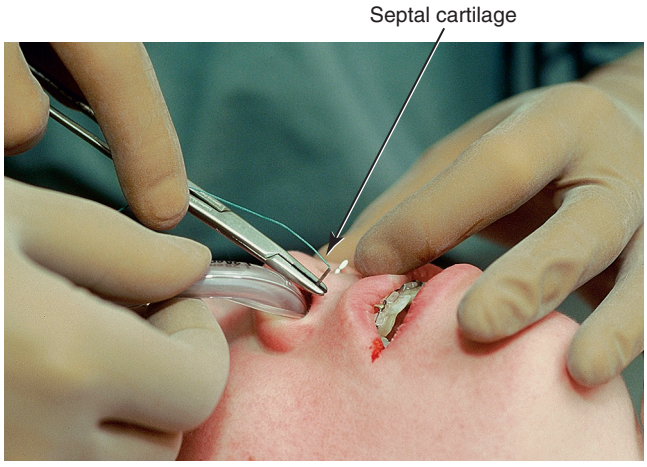
Step 2. A nasotracheal cuffed (Ring-Adair-Elwyn [RAE]) tube is inserted by the anesthesiologist and then secured by the surgeon to the cartilaginous septum with suture (#0 Ethibond). An additional suture (#0 Ethibond) is placed in the midline anterior hair-bearing scalp and then around the endotracheal tube extension over the top of the head to further secure it and to limit tension on the nose (Fig. 15-1).

Step 3. Ophthalmic antibiotic ointment and protective corneal shields are placed beneath the eyelids (or temporary tarsorrhaphies are performed, if preferred) to prevent corneal injury during the operation (Fig. 15-2, *A* through *C*).

Step 4. The anesthesiologist places monitoring equipment for the safe delivery of deliberate hypotensive anesthesia (i.e., arterial line, Foley catheter, large-bore venous lines, pulse oximeter, carbon dioxide monitor, and temperature probe). The bed is then positioned at approximately 15 degrees reverse Trendelenburg (see Chapter 11).

Step 5. Antibiotics (e.g., Cefazolin (Ancef); 15 to 20 mg/kg and up to 1 g) and steroids (e.g., Dexamethasone 0.5 mg/kg/dose, max: 8 mg) are administered intravenously by the anesthesiologist.

Step 6. The head and neck are prepped with povidone–iodine (Betadine) solution. Avoid using soap or alcohol solutions that could irritate the cornea and the mucous membranes. Draping should provide for adequate exposure of the forehead, the eyes,



• **Figure 15-1** Step 2.

the external ears, the face, and the neck. Staples are used to secure the drapes (Fig. 15-3).

Step 7. The mouth and pharynx are suctioned, and a moistened gauze with a radiopaque marker is inserted as a throat pack. The teeth and dorsum of the tongue are cleansed with a sterile toothbrush (1.5% hydrogen peroxide or 0.12% chlorhexidine). The mouth is irrigated with normal saline solution and suctioned.

Step 8. Steroid cream (e.g., betamethasone 0.5%) is applied to the lips to limit edema that could otherwise result from contusion during surgery.

Step 9. Lidocaine solution (Xylocaine 1% with 1 : 100,000 epinephrine) is infiltrated into the lateral vestibules of the mandible, the facial vestibule of the chin, and the labial vestibules of the maxilla.

Cortical Cuts for Sagittal Split Ramus Osteotomies (Video 6:2 and 7:2)

Step 10. A medium rubber mouth prop is placed between the maxillary and mandibular molars on one side to maintain mouth opening. Attention is turned to the lateral vestibule of the contralateral mandible.

Step 11. A. *Incision Option One:* No erupted wisdom tooth for extraction. If there is no erupted wisdom tooth to extract (i.e., if the wisdom tooth is fully impacted, absent, or erupted and is to remain in place), an incision is made with a Bovie electrocautery device or a knife (no. 15 blade) in the depth of the vestibule adjacent to the second molar (Fig. 15-4, *A*). The incision extends both anteriorly and posteriorly for a total length of 4 cm. The incision is carried down to bone. A sufficient cuff of mucosa is maintained adjacent to the gingiva of the molar teeth for relaxed wound closure.

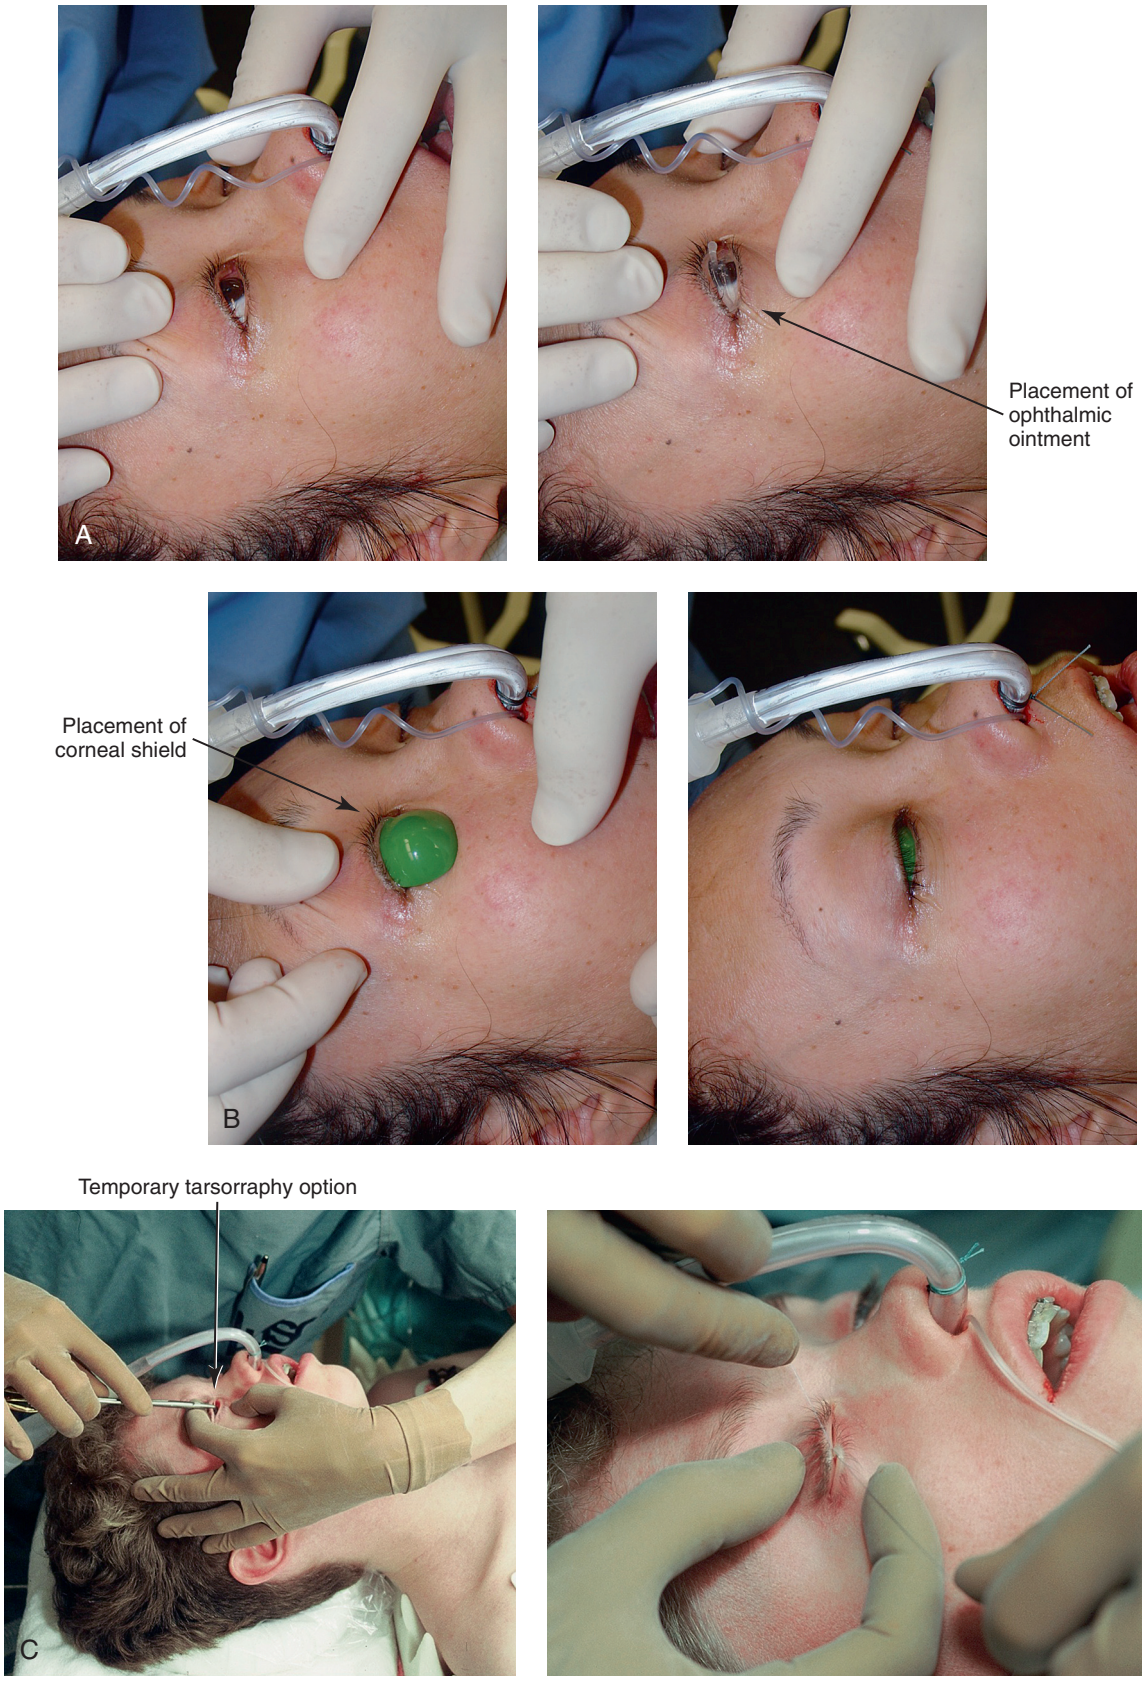
B and C. *Incision Option Two:* Erupted or partially erupted wisdom tooth for extraction. If there is a partially erupted (Fig. 15-4, *B*) or fully erupted (Fig. 15-4, *C*) wisdom tooth to be removed, the incision starts 1 cm distal and lateral to the wisdom tooth and extends to the distobuccal line angle of the tooth. The incision continues anteriorly along the cervical gingival margin of the tooth within the sulcus and then anterior and lateral into the depth of the vestibule. The incision is carried down to bone. A sufficient cuff of mucosa, including part of the papilla, is maintained adjacent to the gingiva of the second molar for relaxed wound closure.

Step 12. The subperiosteal dissection exposes the anterior aspect of the lateral ramus and the posterior body of the mandible down to the inferior border (Fig. 15-5, *A*). The extent of the dissection anterior to the gonial angle depends on the planned buccal extension of the proximal segment. The dissection exposes the anterior superior aspect of the ramus up toward the coronoid process, with stripping of the temporalis muscle tendon (Fig. 15-5, *B C*). The dissection exposes the medial aspect of the ramus superior toward the sigmoid notch and inferior toward the mandibular canal (Fig. 15-6, *A*). (I do not dissect below the inferior alveolar neurovascular bundle or circumferentially around it, because I believe this may cause additional contusion and paresthesia.)

Step 13. Retraction of the soft tissues is performed with a curved Kocher clamp on the coronoid process (superior exposure); a channel retractor superior to the neurovascular bundle (medial ramus exposure); an inferior border retractor placed anterior to the gonial angle (anterior exposure); and a tongue retractor (lingual exposure) (Fig. 15-6).

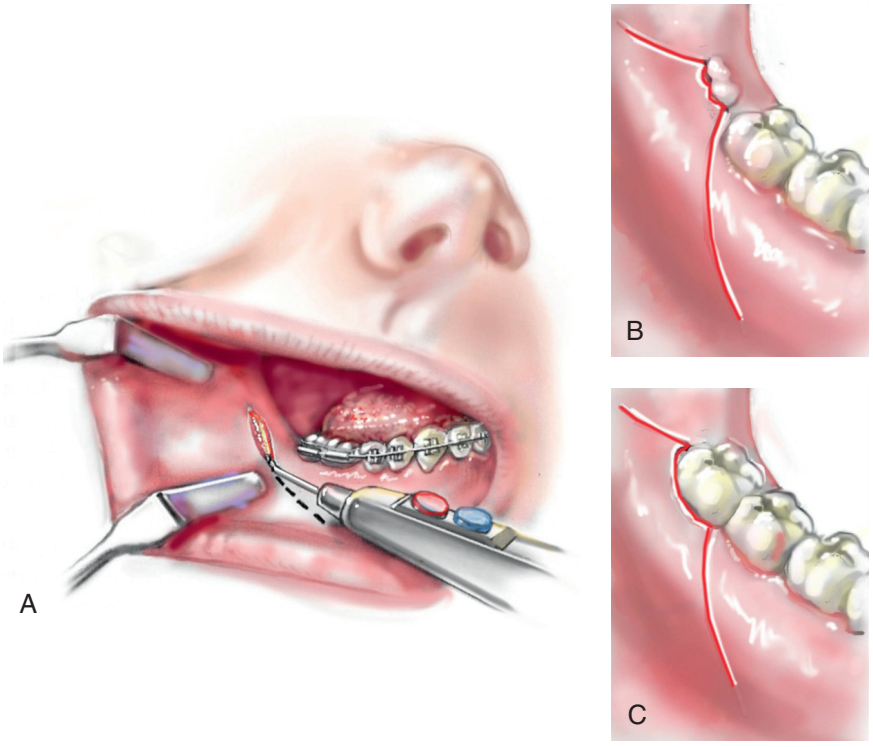
Step 14. With a sterile pencil, the osteotomy lines are marked out for the sagittal splitting of the ramus of the mandible. A reciprocating saw (i.e., with a short, straight blade) completes the cortical osteotomies.

A. The first cut is made horizontally through the medial cortex of the ramus. This is judged to be just superior to the occlusal plane of the mandibular molars and well inferior to the region of the anterior aspect of the ramus, where the medial and lateral cortices join and no longer maintain a medullary cavity. The medial osteotomy need not extend more than 2 cm posterior (Hunsuck modification) (see insert of Fig. 15-6, *A*). By keeping the medial cut "low" (i.e., close to the mandibular molar occlusal surface) and "short" (i.e., only 2 cm back), the incidence of a "bad" split (i.e., with

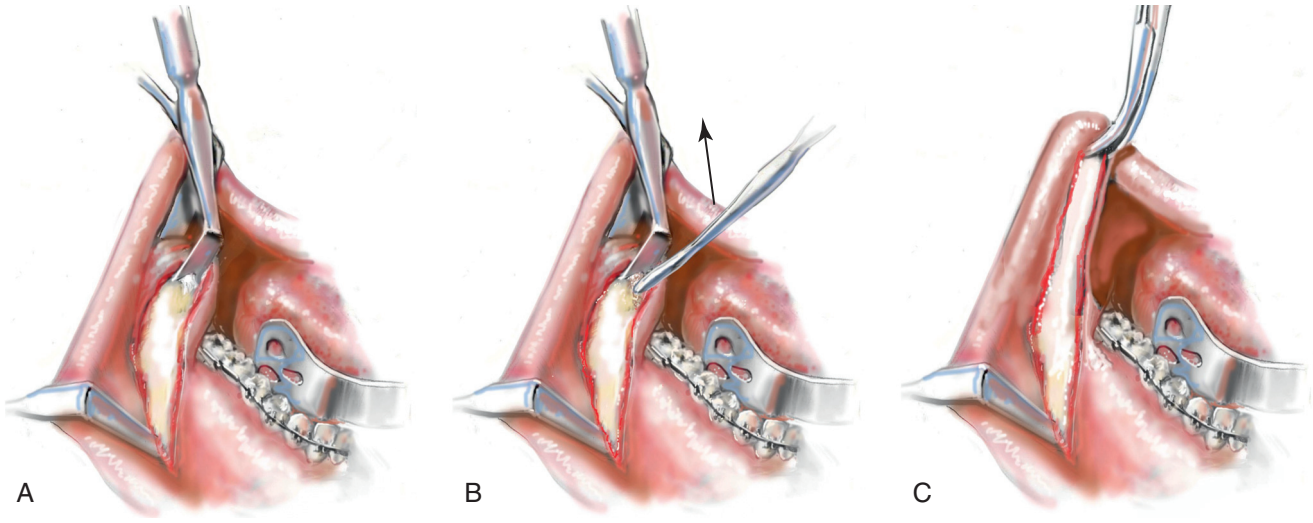


• **Figure 15-2** Step 3.

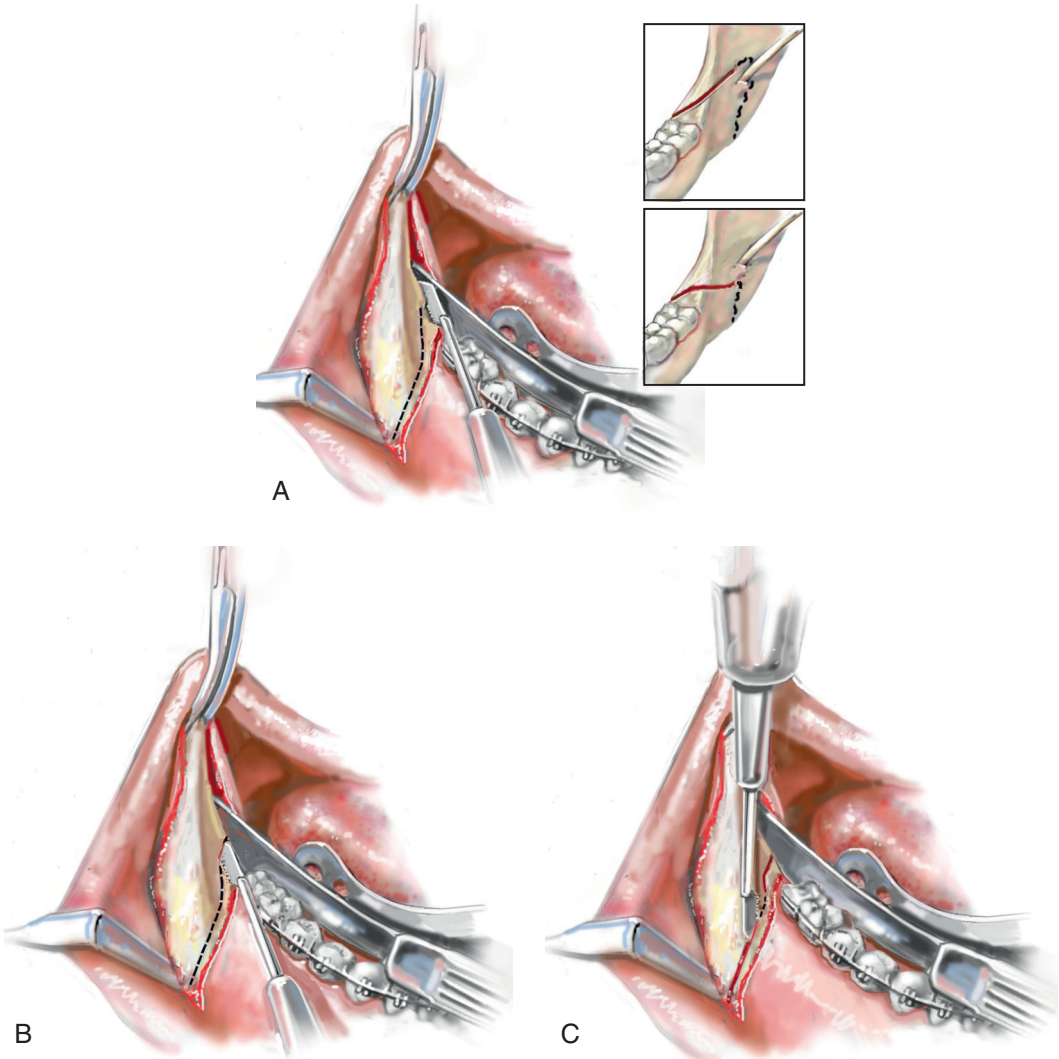
• **Figure 15-3** Step 6.



• **Figure 15-4** Step 11, A, B, and C.



• **Figure 15-5** Step 12.



• **Figure 15-6** Step 14, A, B, and C.

the condyle as a third segment) is greatly reduced.

B. The osteotomy then extends anteriorly and just lateral (buccal) to the molars. It is important that the saw blade penetrate the cortex and enter the medullary cavity in all locations. If the wisdom tooth is impacted, the saw blade will bounce off the wisdom tooth just after penetrating the superior paper-thin cortex (Fig. 15-6, *B*); this will be just lateral to the second molar. The blade will penetrate back into the medullary cavity as the osteotomy progresses anterior past the impacted tooth.

C. The reciprocating saw is then repositioned to complete the vertical cortical osteotomy. The osteotomy location will depend on the planned buccal extension of the proximal segment (i.e., the Dal Point modification.) The vertical osteotomy begins at the inferior border of the mandible, where the inferior alveolar nerve is close to the cortex and prone to laceration (Fig. 15-6, *C*). The osteotomy then continues superiorly to join the cortical osteotomy, which was previously completed lateral to the molars.

COMMENT: When later "splitting" the ramus (see Steps 53 through 58), as the inferior alveolar nerve enters the mandibular foramen, it may remain within either the proximal segment or the distal segment (see Fig. 15-6, *A* inset). Traditional thinking is that the medial osteotomy *must* remain above the mandibular foramen as it extends posterior. I believe that it is more important to keep the medial osteotomy low and short; this is a reliable way to achieve a favorable split with limited risk of the condylar component inadvertently remaining part of the distal segment. After the low and short split is completed, I do not favor the automatic need to completely remove all aspects of the inferior alveolar nerve that may remain within the proximal segment. This is especially true at the mandibular foramen location. I do not drill out or curette the inferior alveolar nerve from the proximal segment unless it would otherwise be under tension after repositioning the distal segment. In my experience, however, this is not usually the case.

Step 15. If the wisdom tooth is erupted and is to be removed, then the extraction is completed now or just before the cortical osteotomies; doing so before the actual split will limit a fracture of the lingual plate that may otherwise occur during dental extraction. A rotary drill with a tapered fissure bur may be used to judiciously remove bone adjacent to the tooth and to section the tooth to facilitate an atraumatic extraction.

Step 16. The wound is irrigated and suctioned. The retractors are removed, and two 1 inch × 3 inch cottonoids are placed for packing (i.e., hemostasis). One is placed along the medial ramus, and the other is placed along the lateral body of the mandible.

Step 17. Attention is turned to the contralateral ramus of the mandible, and identical procedures to those described in Steps 10 through 16 are carried out.

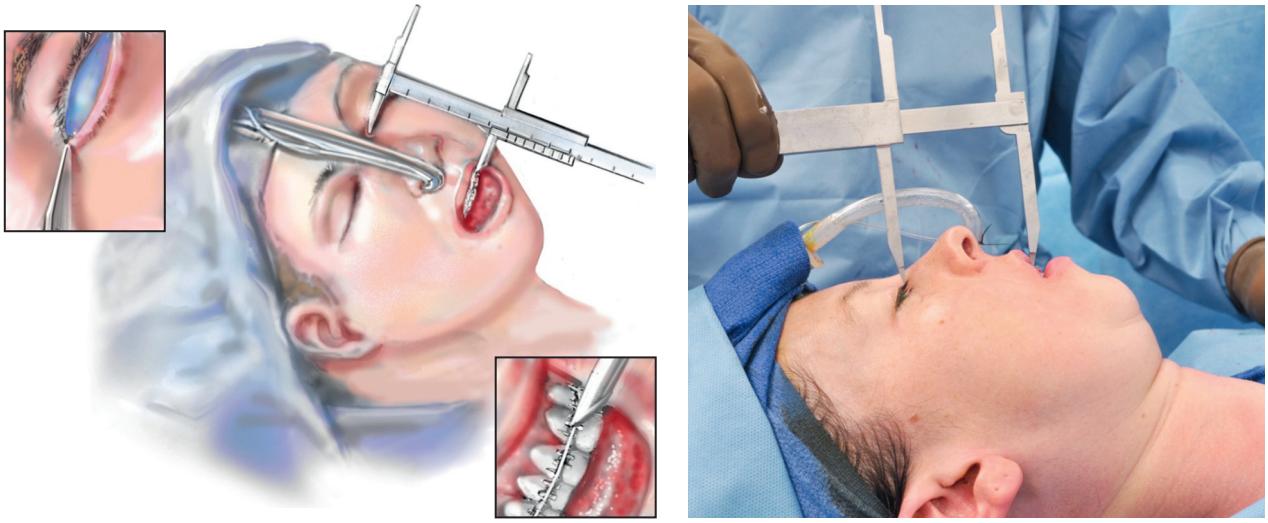
Maxillary (Le Fort I) Osteotomy
(Video 6:3 and 7:3)

Step 18. With the use of a Tessier caliper, the vertical distance (height) between the medial canthus and the mid-maxillary incisor crown is measured on the left and right sides and recorded; this generally measures between 55 mm and 70 mm (Fig. 15-7). This is a reproducible relative measure of the anterior vertical maxillary height (see Chapter 12).

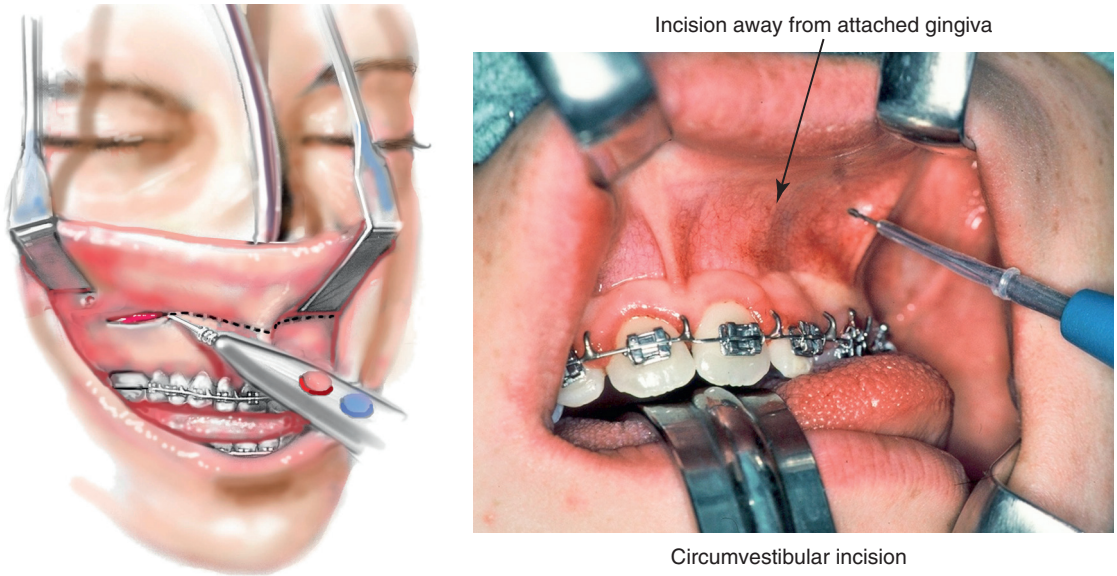
NOTE: If 70 mm is the baseline measurement and 3 mm of vertical intrusion at the incisors is a surgical objective, then, after maxillary repositioning, 67 mm should be the new measurement before the placement of fixation across the Le Fort I osteotomy.

Step 19. Attention is turned to the vestibule of the maxilla on one side. Two medium "toed-in" retractors are used to retract the lip and cheek and thus expose the vestibule. A circumvestibular incision is initiated from the zygomatic buttress region anteriorly toward the midline (Fig. 15-8). It is useful to remain deep in the vestibule and to leave a full cuff of mucosa adjacent to the attached gingiva of the teeth. The most posterior aspect of the incision remains just anterior to and on the dental (vestibular side) of the visualized parotid duct. The incision is made with a Bovie electrocautery device or a knife (#15 blade). Once the incision is made through the mucosa the knife is directed toward the dentoalveolar region and down to bone. This will avoid injury to the infraorbital nerve and limit the exposure of the buccal fat pad.

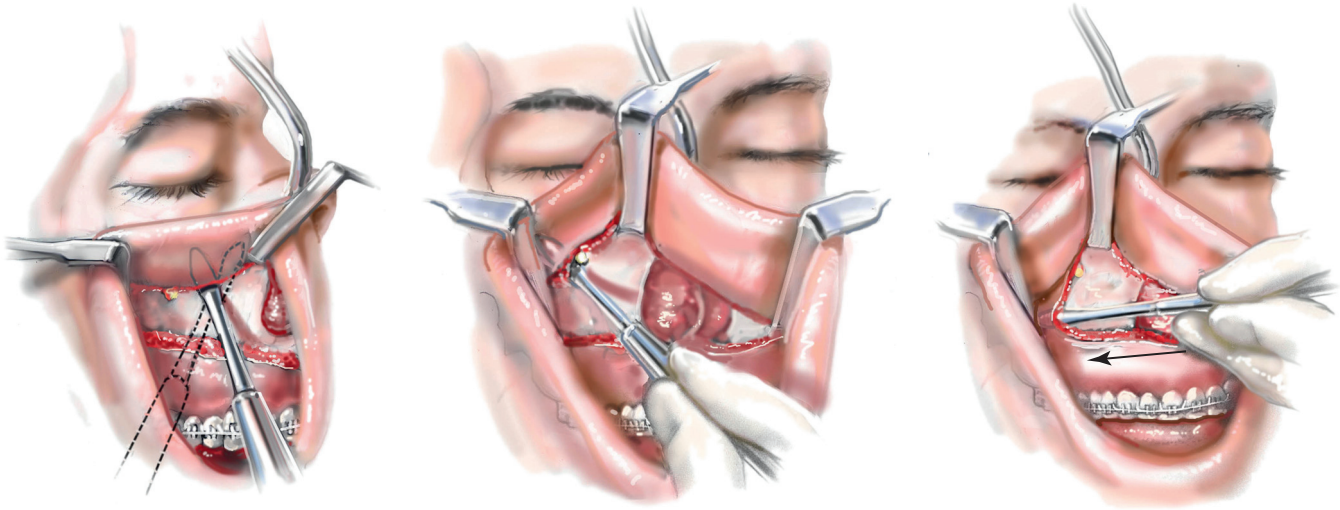
Step 20. Straight and curved elevators are used for the subperiosteal dissection of the anterior maxilla extending to and on either side of the infraorbital nerve; extending medially to expose the pyriform rim, the floor of the nose, and the anterior nasal spine; and extending posterior to the pterygomaxillary junction. A long "toed-out" retractor is placed subperiosteally in the pterygomaxillary space (Fig. 15-9).



• **Figure 15-7** Step 18.



• **Figure 15-8** Step 19.



• **Figure 15-9** Step 20.

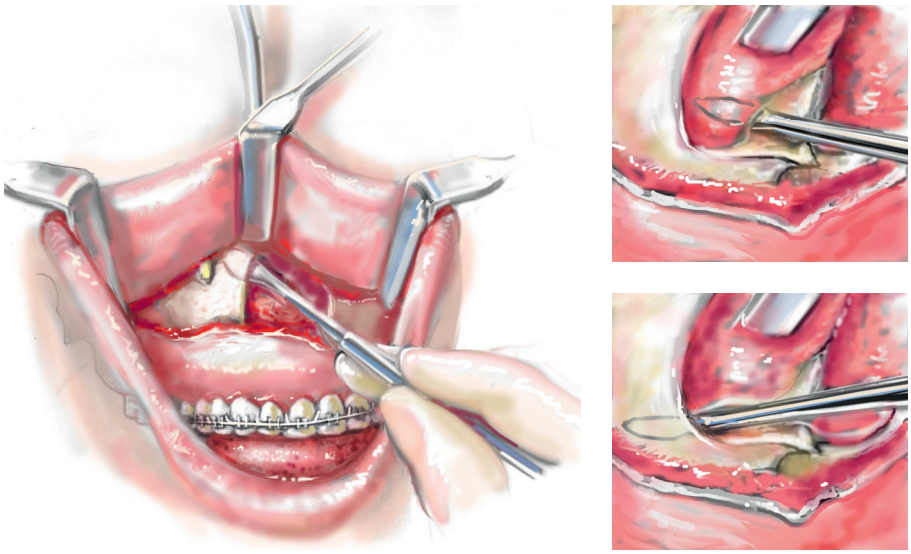
Step 21. The two medium toed-in retractors are shifted to the contralateral side of the maxilla, and the identical incision, dissection, and exposure are accomplished as described in Steps 19 and 20.

Step 22. Straight and curved elevators are used to further separate the nasal mucosa from each lateral nasal wall; the anterior nasal spine from the cartilaginous septum; and the nasal mucosa from the floor of the nose (Fig. 15-10).

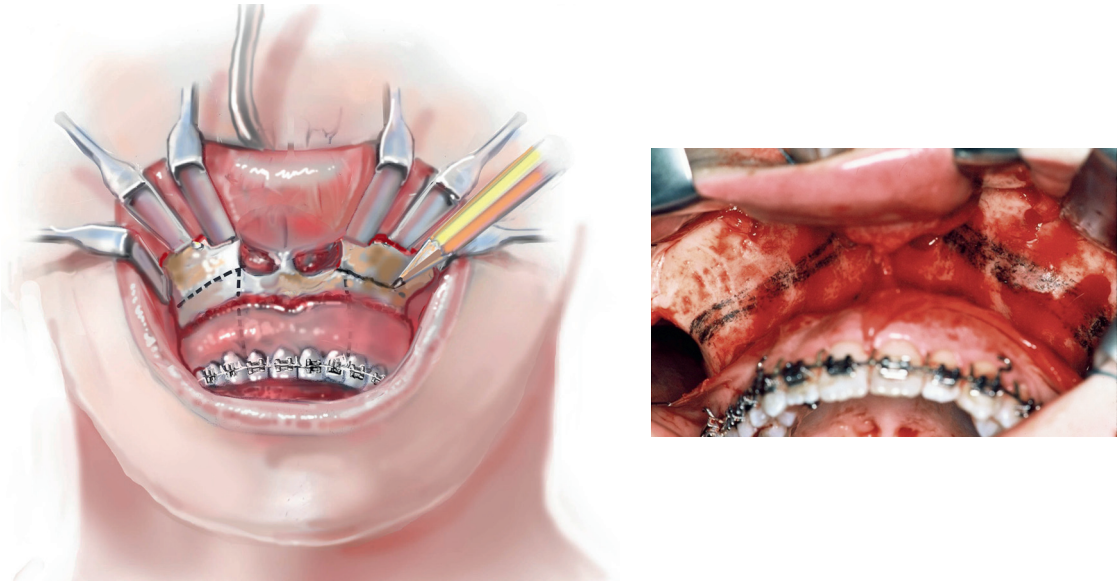
Step 23. With four medium toed-in retractors (one on either side of the infraorbital nerve on each side of the maxilla) and two long toed-out retractors (one in each pterygomaxillary junction) in place, the anterior maxilla is fully visualized. A sterile pencil is used to mark the location for the horizontal Le Fort I osteotomy (Fig. 15-11). If significant maxillary intrusion is planned, a second parallel osteotomy line is marked out. The lower marking (i.e., the osteotomy site) is placed to be within the sinus, above the roots of the teeth, into each lateral nasal aperture, and below each zygomatic buttress. If an ostectomy is to be preformed, the upper marking is made superior and parallel to the lower marking and below the infraorbital nerves (Fig. 15-11).

Segmentation of the Maxilla

Step 24. If segmentation of the maxilla is to be completed, the interdental osteotomies are initiated before down-fracture. This provides a stable "workbench" for the initiation of each interdental osteotomy.



• **Figure 15-10** Step 22.



• **Figure 15-11** Step 23.

The interdental osteotomies are typically made either between the lateral incisor and the canine on each side (Fig. 15-12, *A*) or between the central incisors (Fig. 15-12, *B*). The subperiosteal dissection of the gingival cuff provides adequate exposure of each interdental osteotomy location without the need for direct mucosa incisions. Each interdental osteotomy site is marked with a sterile pencil. The osteotomy is then initiated with an oscillating saw (i.e., a short fan blade on a long shaft) and later deepened after down-fracture with the oscillating saw (i.e., a longer fan blade on a long shaft).

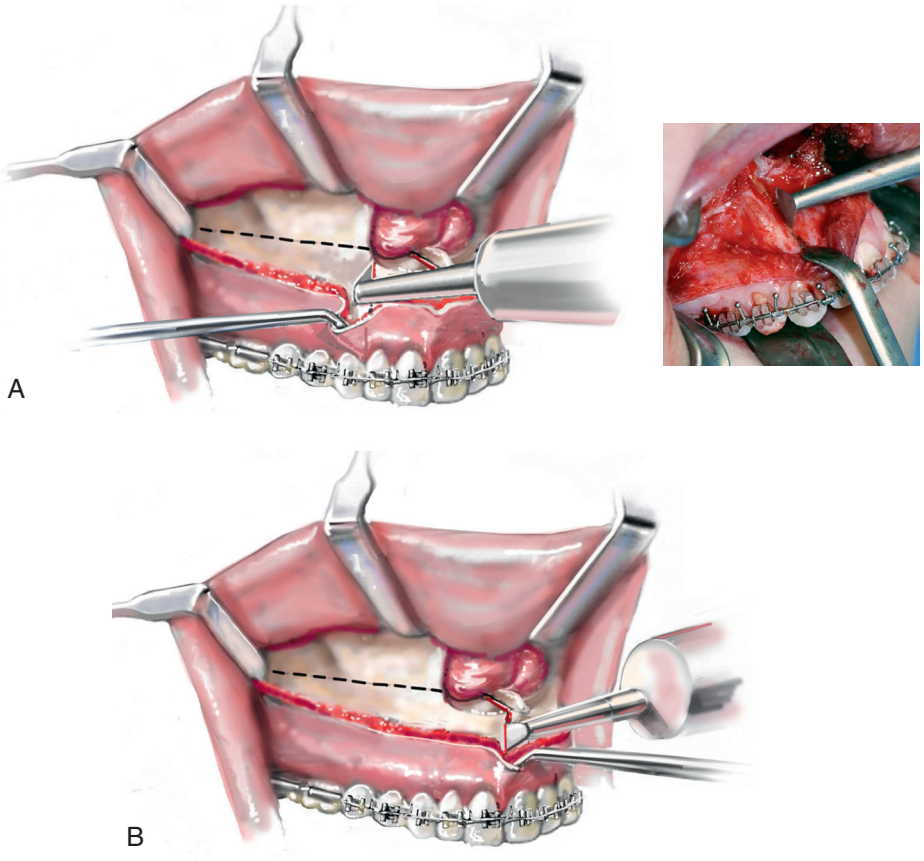
NOTE: The lateral incisor and canine roots—and, to a lesser extent, the two central incisor roots—are naturally divergent. Therefore, there is no advantage or need for the orthodontist to create a gap for the interdental osteotomy. Perforation into the periodontal ligament space with injury to the dental roots when completing these interdental osteotomies should be an uncommon occurrence.

Maxillary (Le Fort I) Osteotomy: Continued

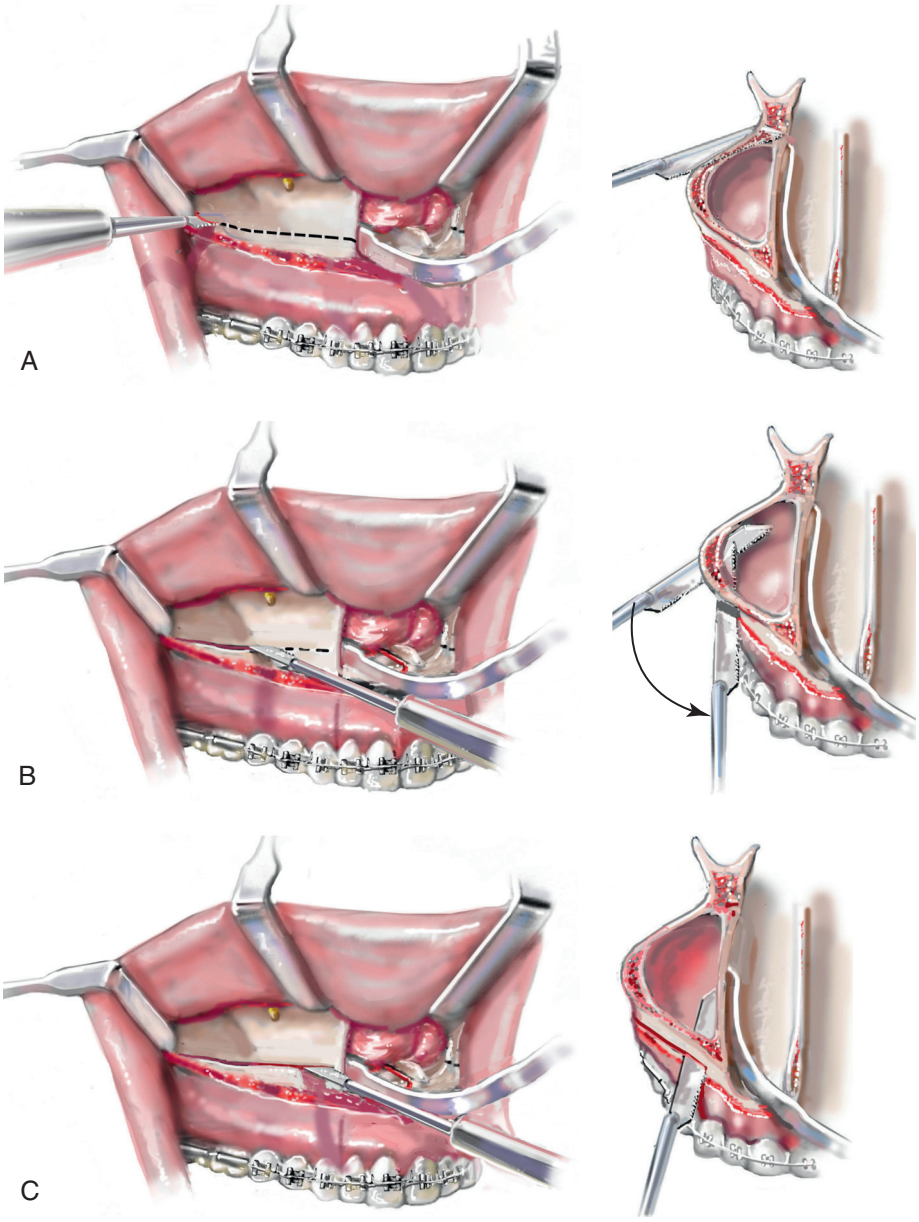
Step 25. With a reciprocating saw (i.e., a long straight blade), the Le Fort I horizontal osteotomy is completed through the lateral, anterior, and medial maxillary walls on each side (Fig. 15-13, *A* through *C*). Before the medial maxillary osteotomy is completed, the lateral nasal mucosa is protected with a small malleable retractor placed between the lateral nasal wall and the nasal mucosa. Before the lateral maxillary osteotomy is completed, the pterygoid fossa soft tissues are protected with a long, toed-out retractor.

Step 26. With a specialized guarded chisel and mallet, the septum of the nose (i.e., cartilage and bone) is separated from the maxilla. Care is taken to avoid penetration past the septum into the nasopharynx (Fig. 15-14).

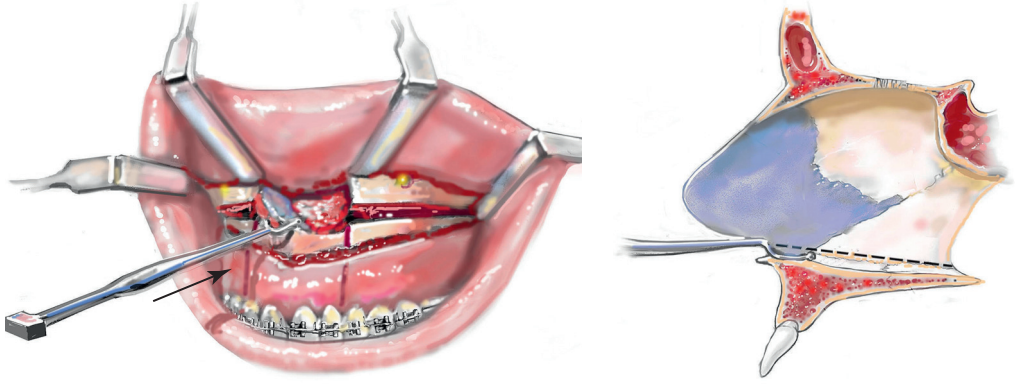
Step 27. With a specialized curved chisel and mallet, the pterygomaxillary suture is separated on each side (Fig. 15-15). Care is taken to avoid injury to the internal maxillary artery or to the pterygoid plexus and to avoid perforation through the palatal mucosa. For a patient with extreme maxillary hypoplasia (e.g., Treacher Collins syndrome), the



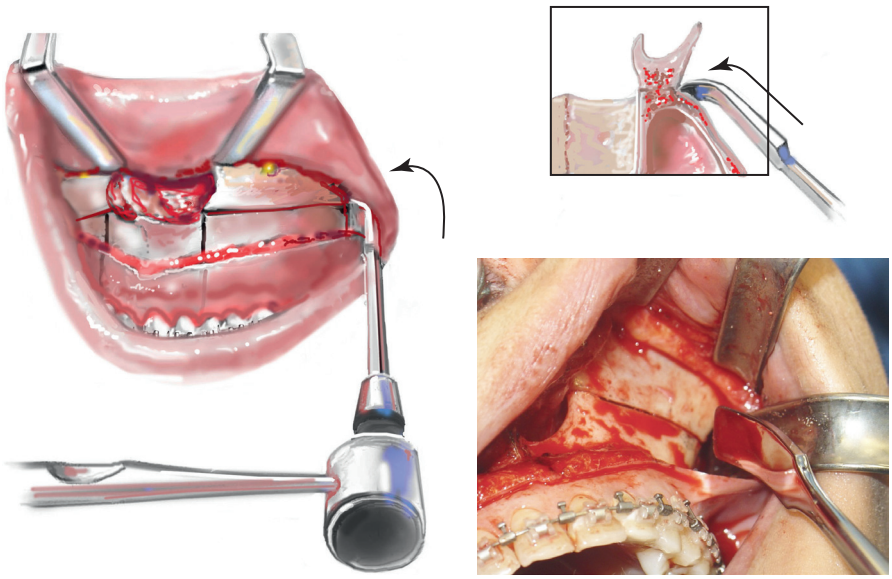
• **Figure 15-12** Step 24.



• **Figure 15-13** Step 25.



• **Figure 15-14** Step 26.



• **Figure 15-15** Step 27.

chisel may be within millimeters of the optic foramen and the optic nerve.

Step 28. With a Tessier (blunt) zygomatic hook placed on the ledge of the nasal sill, force is applied to "down-fracture" the Le Fort I osteotomy unit. While down-fracturing, a Frazier suction tip and a periosteal elevator are used by the assistant to further separate and to limit the tearing of the nasal mucosa (Fig. 15-16).

Step 29. After down-fracture, the maxillary sinus mucosa is generally stripped off of its bony surfaces with a Frazier suction tip and a hemostat (Fig. 15-17). This is done to remove chronic inflammatory tissue (polyps) from the sinus and to reduce hemorrhage.

Step 30. Placing the Tessier (blunt) hook behind the maxillary tuberosity and applying anterior and contralateral directed force to one side at a time assists with the disimpaction of the maxilla (Fig. 15-18). The advantage of the Tessier hook is that it assists with the mobilization of the maxilla without contusion of the palatal mucosa, which may occur with standard (Rowe) nasomaxillary disimpaction forceps. When disimpacting with the Tessier hook behind the tuberosity, the surgeon's other hand is used to grip the anterior maxilla (rather than the teeth) and to apply simultaneous anterior and contralateral force. This is helpful to prevent the fracturing of the tuberosity by the Tessier hook. This is repeated on each side two times to achieve maximum disimpaction. During this process, the assistant to the surgeon stabilizes the patient's head with one hand over each ear. For a maxillary disimpaction that requires more extensive advancement, the Rowe forceps may be required.

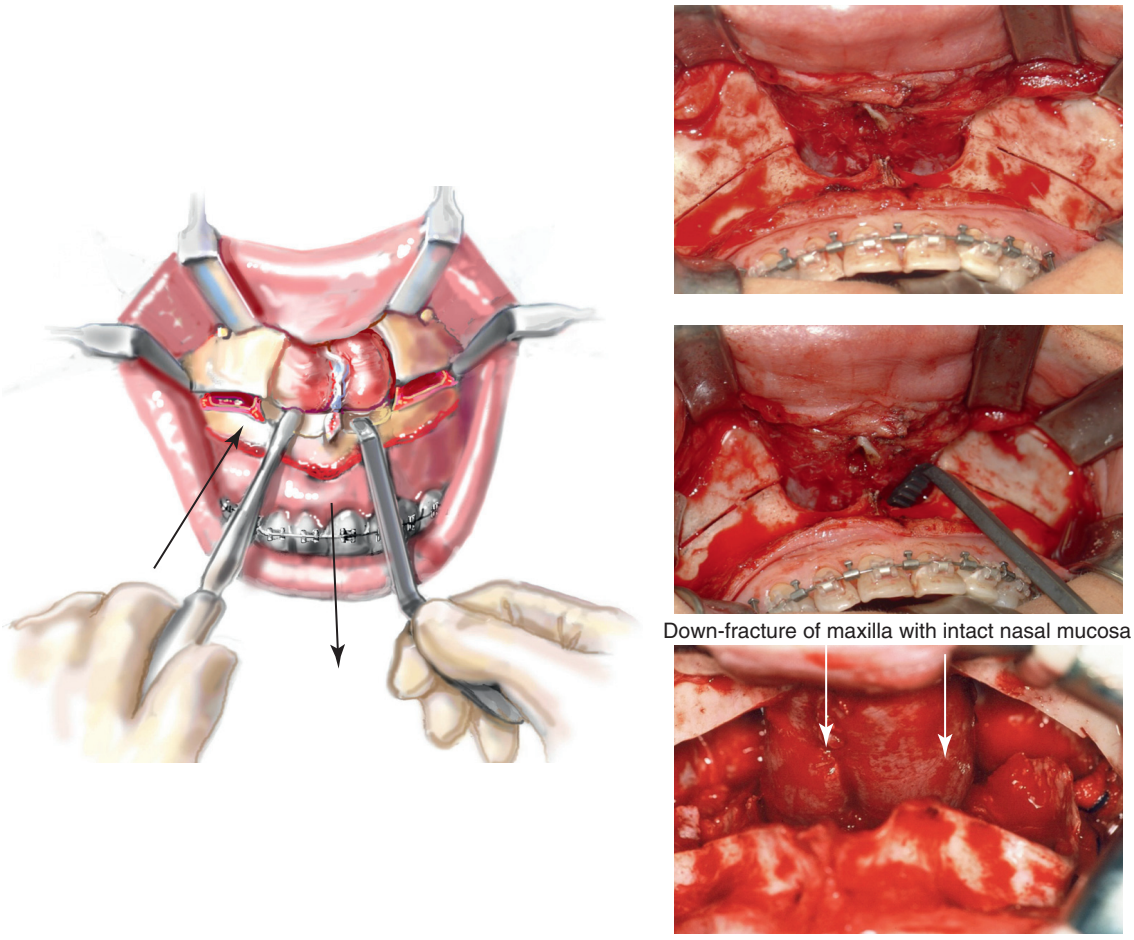
Septoplasty and the Reduction of the Inferior Turbinates (Video 6:4 and 7:4)

Step 31. When indicated on the basis of the patient's history and clinical examination, attention is turned to the removal of the deviated portions of the septum of the nose that are causing blockage of the airway.

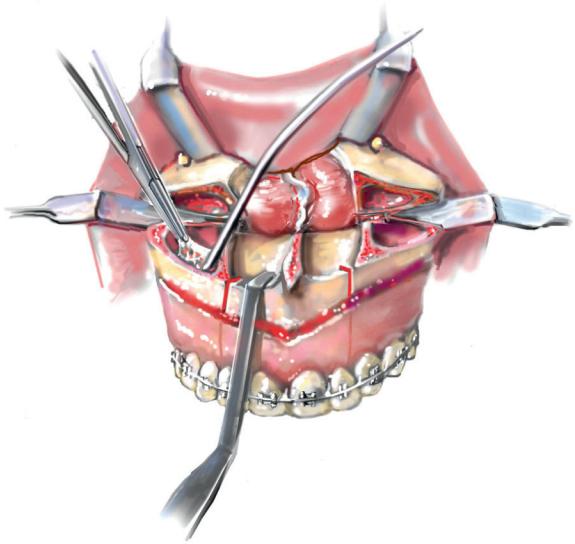
A. With an elevator, the submucosal dissection of the cartilaginous septum (i.e., the quadrangular cartilage) and the bony septum (i.e., the vomer and the perpendicular plate of the ethmoid) is carried out (Fig. 15-19, *A*).

B. The deviated and thickened aspects of the cartilaginous septum and the bony septum are resected with a rongeur (Fig. 15-19, *B*). The more anterior components of the cartilaginous septum that provides needed support to the nasal dorsum and the tip are not disturbed. This includes at least 1 cm of the dorsal and caudal cartilage. When a maxillary intrusion (i.e., for impaction) is planned, even if septoplasty is not required to correct chronic nasal obstruction, the inferior aspect of the septum (i.e., the bone and cartilage) is removed to prevent buckling.

Step 32. When indicated by the patient's history and physical examination, attention is turned to reducing each hypertrophic inferior turbinate that is causing blockage of the airway. An incision is made through the nasal mucosa just below and parallel to each turbinate (Fig. 15-20, *A*). If the nasal mucosa was torn during down-fracture, the laceration is used and may be extended for improved turbinate exposure. Each enlarged



• **Figure 15-16** Step 28.



• **Figure 15-17** Step 29.

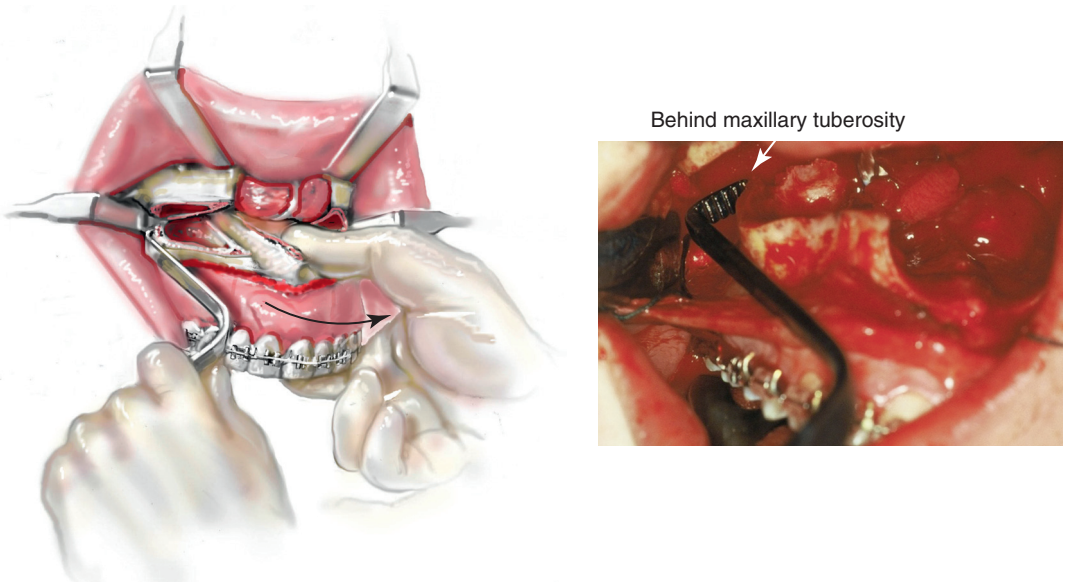
inferior turbinate is visualized (Fig. 15-20, *B*), and the inferior aspect of each is resected with a straight Mayo scissors (Fig. 15-20, *C*). Hemostasis is obtained along the cut edge of each turbinate with the Bovie electrocautery device (Fig. 15-20, *D*). The nasal mucosa is reapproximated with interrupted sutures (3-0 Vicryl [polyglactin 910]) to create a closure that is as watertight as possible (Fig. 15-20, *E*).

NOTE: To prevent a fire in the operative field, if there are any air leaks around the nasotracheal tube, then the electrocautery device is not used.

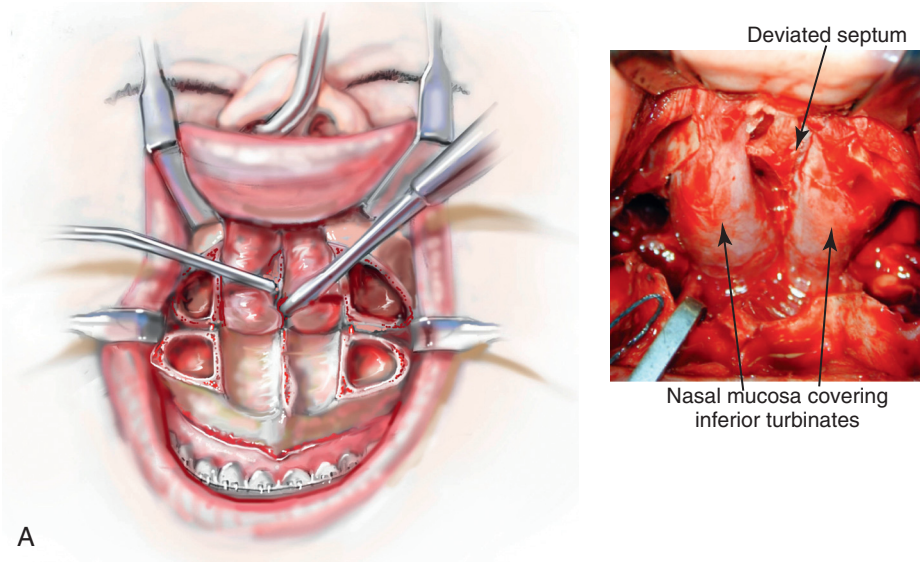
Removal of the Maxillary Wisdom Teeth (Video 6:5)

Impacted Wisdom Teeth

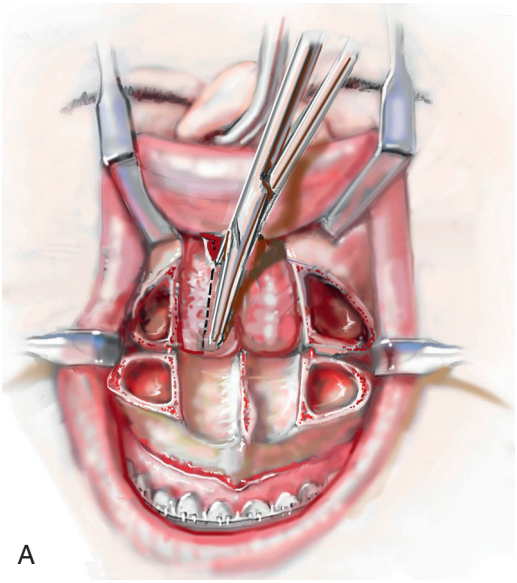
Step 33. A. If indicated, each bony impacted maxillary wisdom tooth is removed through the sinus floor (Fig. 15-21). A rotary drill with a small watermelon bur is used to remove bone from the sinus floor that is directly over the impacted



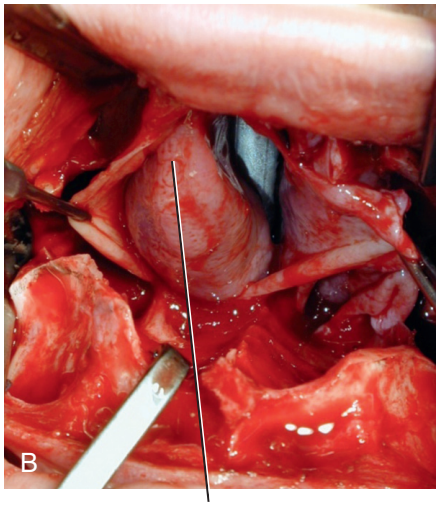
• **Figure 15-18** Step 30.



• **Figure 15-19** Step 31, A and B.

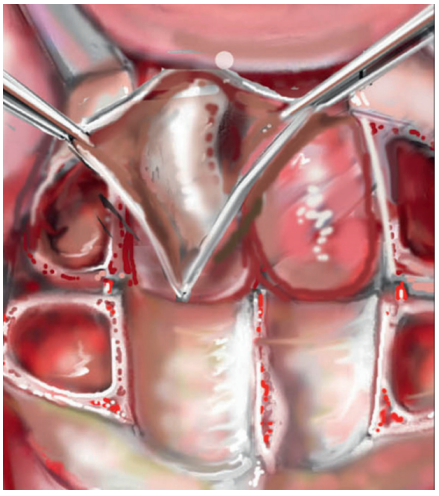


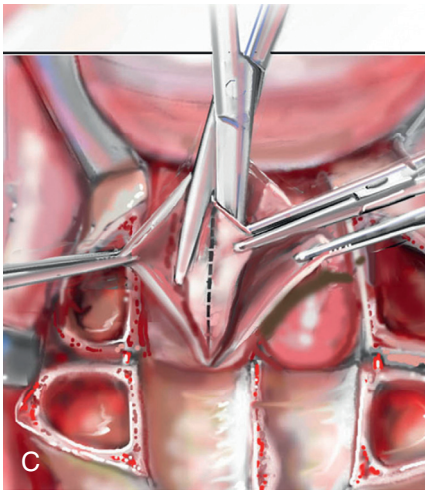
A



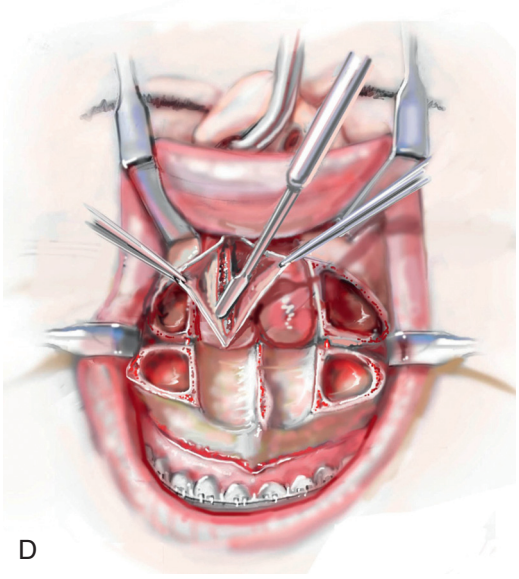
B

Inferior turbinate exposed after elevation of nasal mucosal flaps

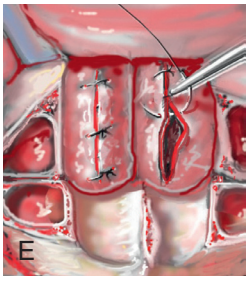




C

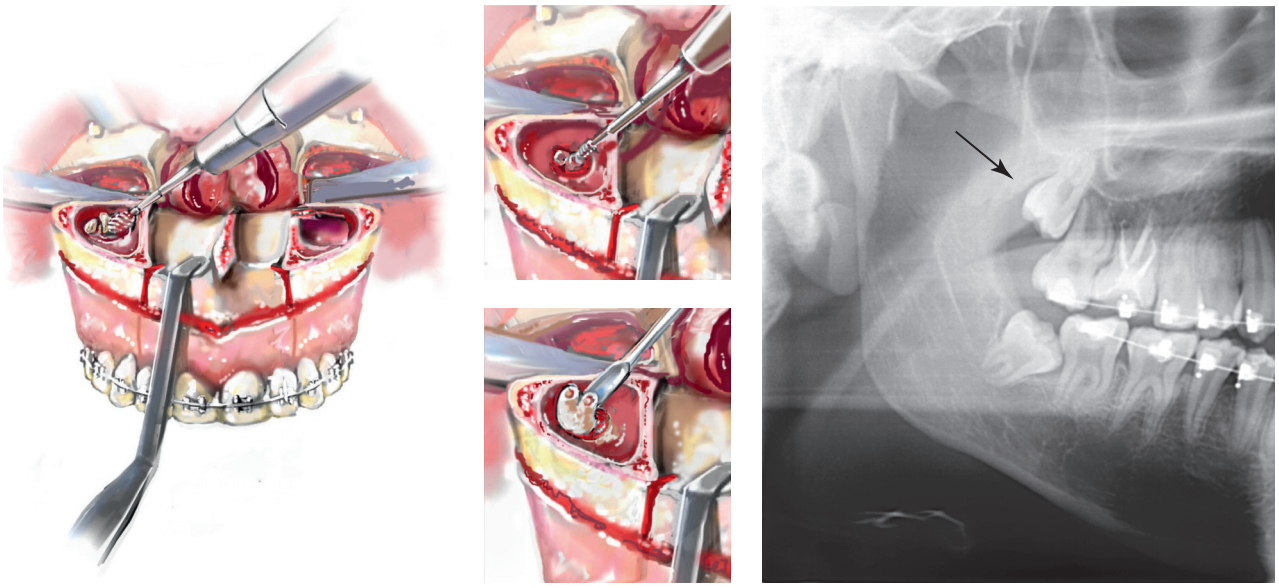


D



E

• **Figure 15-20** Step 32.



• **Figure 15-21** Step 33.

tooth. Next, using a rotary drill with a tapered fissure bur, bone is removed adjacent to the impacted tooth. Depending on the extent of tooth development, the impacted wisdom teeth may also be sectioned to assist with removal. A dental elevator is used to remove the tooth. Perforation through the palatal mucosa is an uncommon occurrence.

Erupted Wisdom Teeth

B. If indicated, each erupted maxillary wisdom tooth is removed before down-fracture. This provides a stable "workbench" at the time of extraction. To preserve maximum circulation to the down-fractured maxilla, it is important to minimize the disruption of the adjacent palatal and labial mucosa at the time of extraction.

Segmentation of the Maxilla: Continued

If segmentation of the maxilla is to be carried out, the interdental cuts that were initiated previously are completed during this stage.

Three Segments

Step 34. A. Description of a three-piece Le Fort I osteotomy with interdental cuts between the lateral incisor and the canine on each side connected to parasagittal osteotomies through the hard palate:

(1) The parasagittal maxillary osteotomy is completed through the down-fracture using a reciprocating saw with a short, straight blade. The osteotomy is from the posterior edge of the hard palate anteriorly to the pre maxillary region (Fig. 15-22, *A-1*).

(2) If the planned posterior arch-width expansion is significant, then a second parasagittal osteotomy is also completed on the contralateral side (Fig. 15-22, *A-2*). The two parallel parasagittal osteotomies allow for a more tension-free expansion than a single osteotomy.

(3) The previously initiated interdental osteotomies are deepened using an oscillating saw with a longer, fan blade on a long shaft (Fig. 15-22, *A-3*).

(4) The oscillating saw with a longer, fan blade on a long shaft is also used to connect each interdental osteotomy to the parasagittal osteotomy along the floor of the nose at the level of the incisal foramen (Fig. 15-22, *A-4*).

(5) A fine chisel (i.e., 5 mm or 7 mm in width) is placed into the interdental osteotomy on the same side as the parasagittal osteotomy, and an elevator is placed into the parasagittal palatal osteotomy (Fig. 15-22, *A-5*). Twisting the elevator and chisel simultaneously assists with the splitting of the maxilla into segments.

(6) The fine chisel (i.e., 5 mm or 7 mm) is then placed into the other interdental osteotomy site, and an elevator is placed in the nasal floor osteotomy site. With a twisting motion, separation is completed (Fig. 15-22, *A-6*). Perforation through the palatal mucosa (when completing

• **Figure 15-22B, cont'd** Step 34, B, Part 1 through Part 3.

the parasagittal palatal osteotomy) with a reciprocating saw may occur. The creation of a permanent palatonasal fistula or the compromise of the circulation to the maxillary segments should be an uncommon occurrence (see Chapter 16).

Two Segments

B. Description of a two-piece Le Fort I osteotomy with an interdental cut between the central incisors connected to parasagittal osteotomies through the hard palate:
   (1) The parasagittal palatal osteotomy is completed through the down-fracture using a reciprocating saw with a short, straight blade from the posterior edge of the hard palate anteriorly to the level of the incisive foramen (Fig. 15-22, *B-1*). If the planned posterior arch-width expansion is significant, then a second parasagittal osteotomy is also completed on the contralateral side.
   (2) The previously initiated interdental osteotomy is deepened using an oscillating saw with a longer, fan blade on a long shaft (Fig. 15-22, *B-2*).
   (3) A fine chisel (i.e., 5 mm or 7 mm in width) is placed into the interdental osteotomy, and an elevator is placed into the parasagittal osteotomy. Twisting both simultaneously assists with the splitting of the maxilla into the two segments (Fig. 15-22, *B-3*). Perforation through the palatal mucosa when completing the parasagittal palatal osteotomy may occur. The creation of a permanent palatonasal fistula or the compromise of the circulation to the maxillary segments should be an uncommon occurrence.

Maxillary Le Fort I Osteotomy: Continued
(Video 6: 6-10 and 7: 5-9)

Step 35. The maxillary segments are next secured into the prefabricated acrylic intermediate occlusal splint with the use of 26-gauge wire placed through interdental drill holes in the splint and around the orthodontic arch wire (Fig. 15-23).

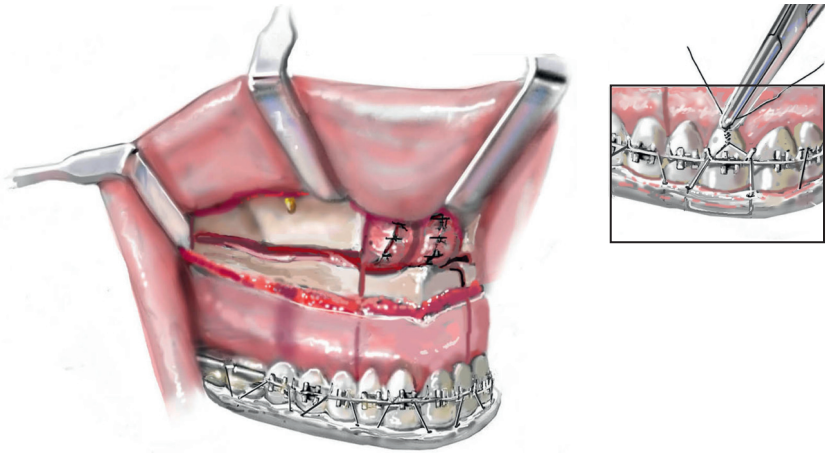
Step 36. The maxillary segments are secured to the mandible in the occlusion established by the "intermediate" splint with the use of 26-gauge wire loops passed around hooks located on the orthodontic arch wires (Fig. 15-24).

Step 37. With the condyles seated in the terminal hinge position (i.e., the same position that they were in when capturing centric relation in the office setting), the maxillomandibular complex is rotated to achieve the vertical dimension that was preoperatively determined (Fig. 15-25, *A*).

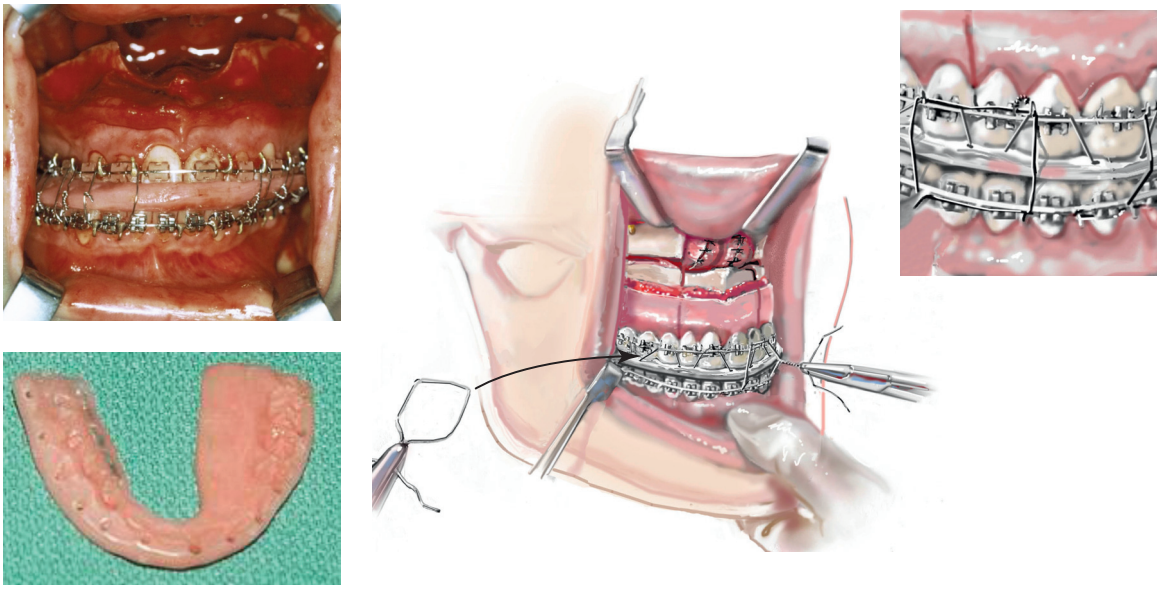
A. If vertical shortening (impaction) of the maxilla is planned, this will require the removal of bone interferences with rongeurs or using a rotary drill with a watermelon bur.

B. The Tessier caliper is used to measure the anterior vertical dimension (i.e., the anterior facial height) of the midface (i.e., the medial canthus to the mid-maxillary incisor on each side) to confirm that the desired vertical height is achieved (Fig. 15-25, *B*).

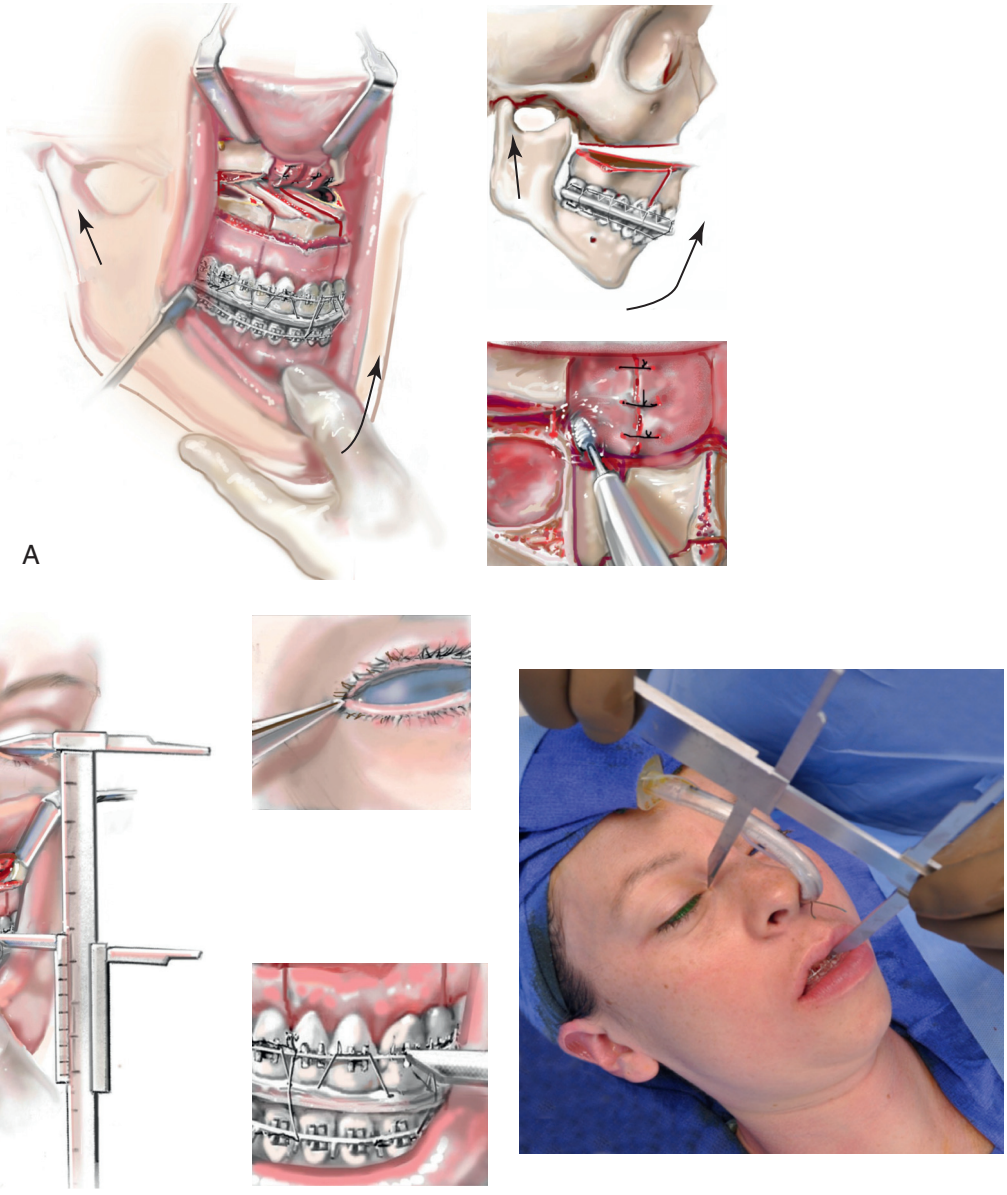
Step 38. With the condyles remaining in the terminal hinge position (i.e., the same position that they were in when capturing centric relation in the office setting) and with the maxilla in the preferred vertical location, appropriately sized and individually contoured L-shaped titanium plates (one by one) are most frequently placed across each zygomatic buttress and at each lateral nasal rim and secured with titanium screws (1.7 mm in diameter and 4 mm in length) (Fig. 15-26).



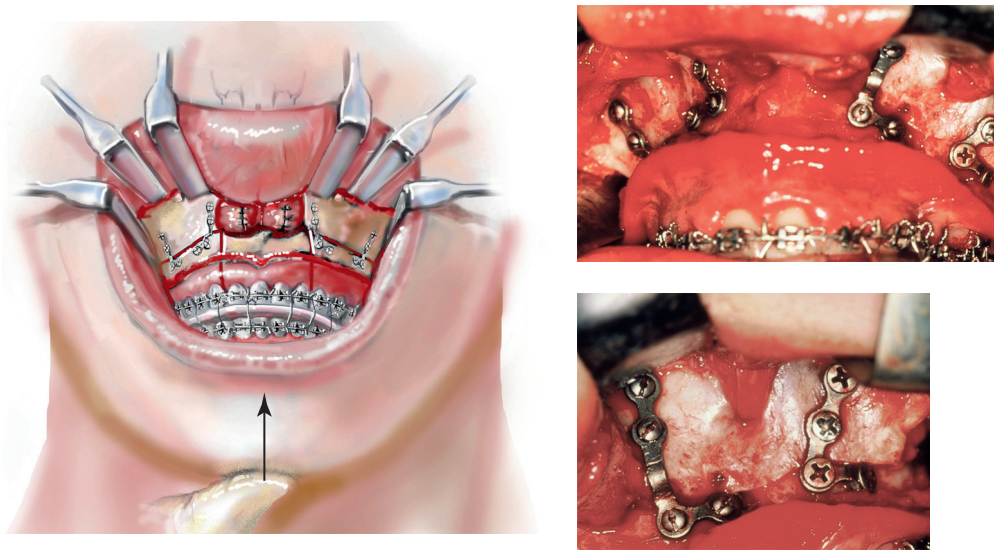
• **Figure 15-23** Step 35.



• **Figure 15-24** Step 36.



• **Figure 15-25** Step 37, A and B.

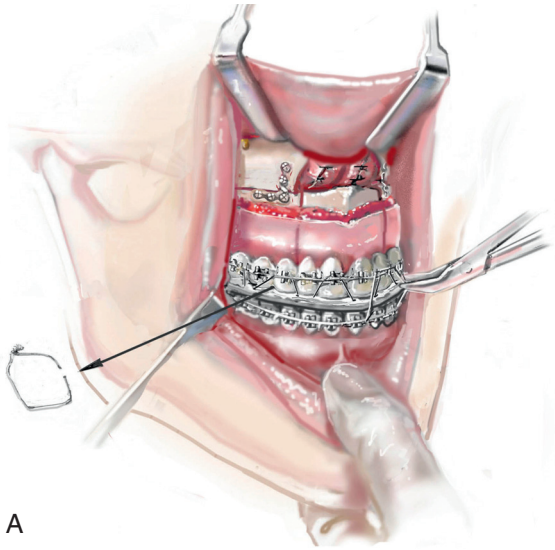


• **Figure 15-26** Step 38.

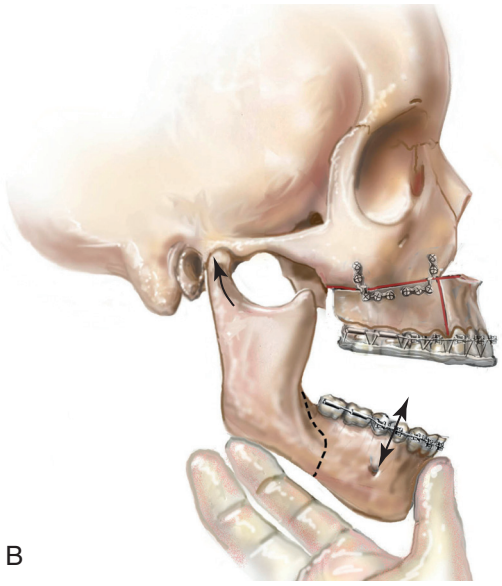
Step 39. A. The jaws are unwired (Fig. 15-27, *A*).
B. With the condyles seated in the terminal hinge position, the mandible is rotated vertically (up and down) to check the occlusion. The occlusion *must* be found to be even within the intermediate splint (Fig. 15-27, *B*).

Step 40. A. After the occlusion is determined to be even, the intermediate splint is removed.
B. The "final" splint is placed on the maxillary teeth and secured to the orthodontic wire (Fig. 15-28, *A*). This is accomplished with the use of 26-gauge wires passed through the interdental drill holes in the "final" splint and around the orthodontic arch wire (Fig. 15-28, *B*).

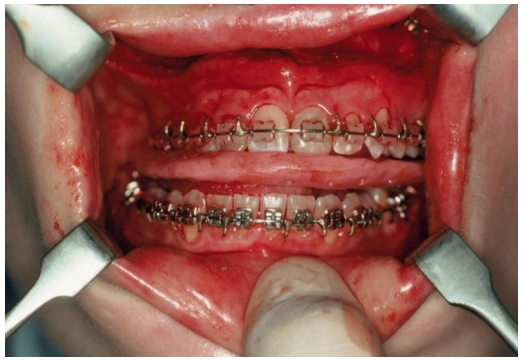
Step 41. When the extent of horizontal advancement and vertical lengthening of the maxilla are judged to be significant, then an interpositional bone graft may be beneficial for the achievement of reliable healing (Fig. 15-29, *A*). In these circumstances, I prefer to use autogenous or allogenic iliac bone graft. A bloc of corticocancellous bone is crafted and tightly wedged into the gap on each side. Each graft is inset in between the pyriform rim and the zygomatic buttress titanium plates (Fig. 15-29, *B*). An additional plate is then contoured to extend from the anterior maxilla above, across the graft, and then onto the alveolar process of the anterior maxilla. Titanium screws (1.2 mm in diameter and 3 mm in length). then secure the plate to the bone (Fig. 15-29, *C*).



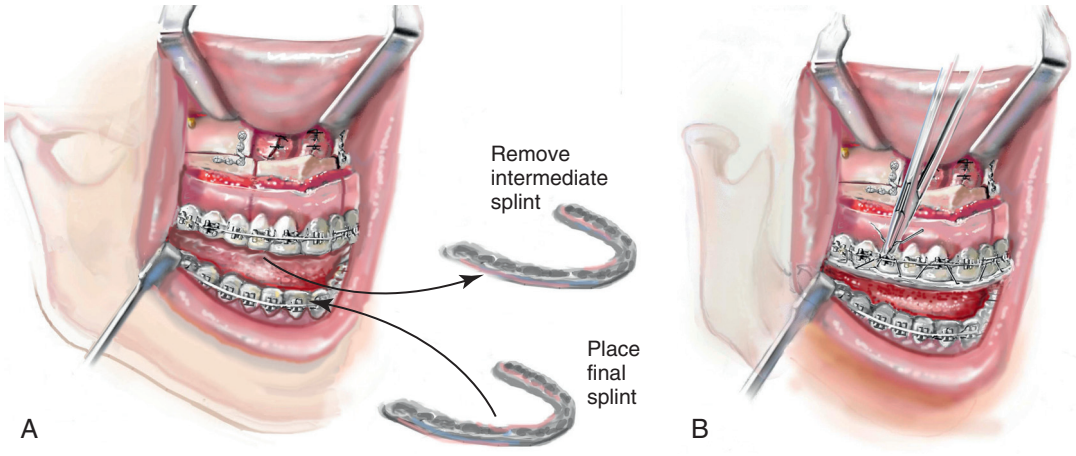
A



B



• **Figure 15-27** Step 39, A and B.



• **Figure 15-28** Step 40, A and B.

Pyriform Rim, Nasal Floor, and Anterior Nasal Spine Recontouring (Video 6:9 and 7:7)

Step 42. The nasal aperture, the floor of the nose, and the anterior nasal spine are inspected. Refinement and recontouring of these structures using a rotary drill with a watermelon bur are frequently beneficial (Fig. 15-30). For example, in the patient with vertical maxillary excess (i.e., long face growth pattern), the deepening and recontouring of the nasal floor, the pyriform rims, and the anterior nasal spine will generally improve nasal airflow (i.e., the correction of a tight nasal inlet and an elevated nasal floor) and also enhance nasal aesthetics (i.e., limit unwanted alar base widening and tip elevation).

Chin Osteotomy (Video 6:11 and 7:10)

Step 43. Attention is next turned to the facial vestibule of the chin. The lower lip is stretched outward to allow for exposure of the vestibule and the visualization of the mental nerve through the mucosa on each side. In the depth of the vestibule, an incision is made with the use of a Bovie electrocautery device or a knife (#15 blade) through the mucosa from cuspid region to cuspid region, stopping just short of the visualized mental nerve on each side (Fig. 15-31). The center two thirds of the incision are next extended down to bone. A full cuff of mucosa and muscle is maintained adjacent to the attached gingiva of the anterior teeth. This should allow for adequate layered wound closure (i.e., involving muscle and mucosa) without resulting periodontal sequelae.

Step 44. Dissection with an elevator exposes the anterior surface of the chin (not completely to the inferior border of the central chin). The dissection continues laterally and remains inferior to the mental nerve, with lateral exposure to the inferior border of the mandible. There is no need to dissect above the mental nerve on either side. If a 360-degree dissection around the nerve is completed, it is more likely that the nerve will be excessively stretched or avulsed.

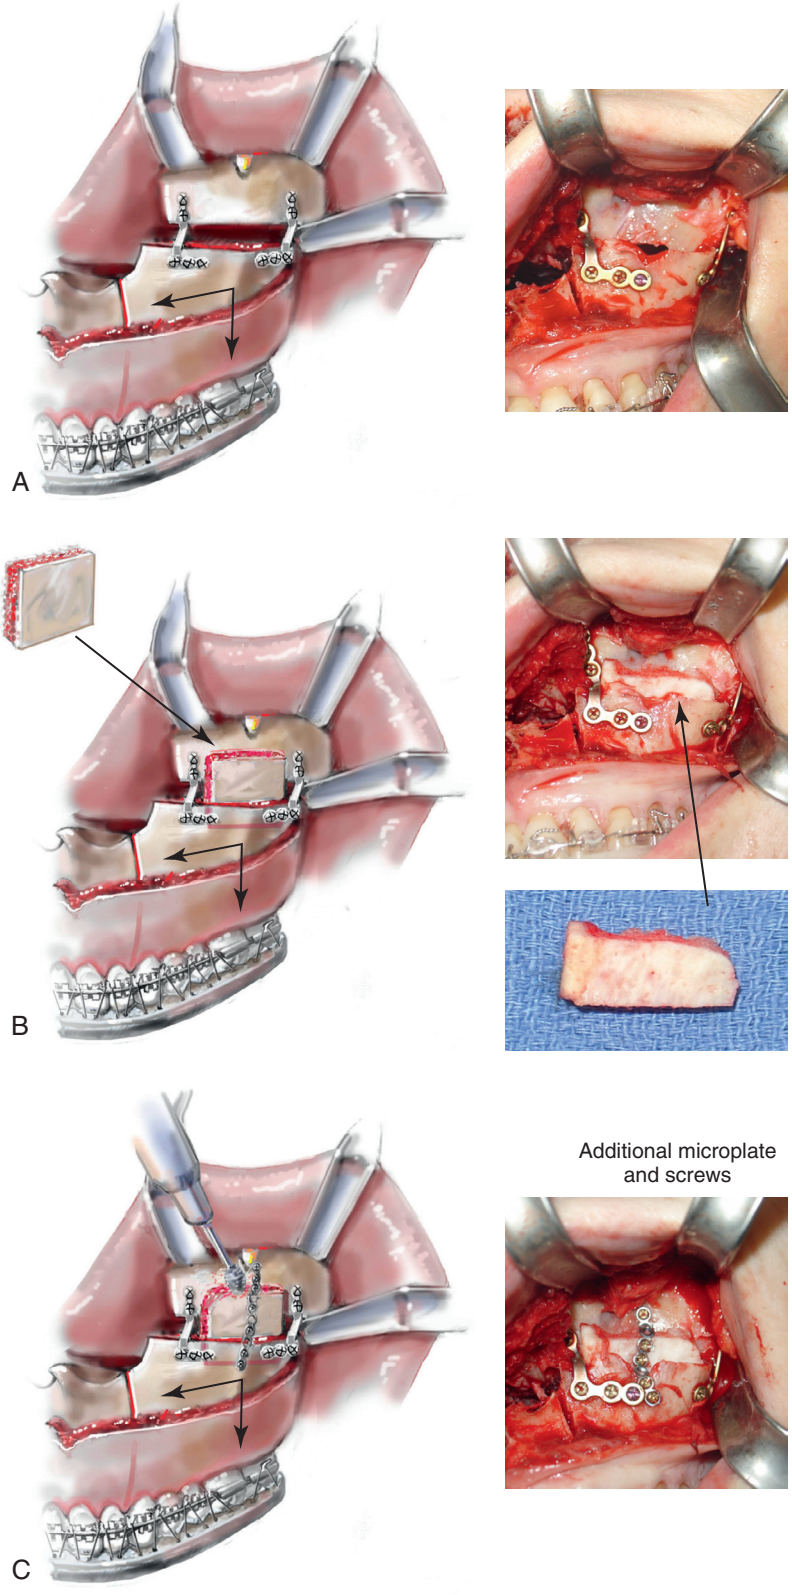
Step 45. A small S-shaped Tessier chin retractor is placed on each side inferior to the mental nerve and laterally to the inferior border. A sterile pencil is used to mark the location of the oblique osteotomy (Fig. 15-32); this should be planned sufficiently below the dental roots and the mental foramen on each side. The exact location of the osteotomy will depend on the presenting chin morphology and the planned reconstruction (i.e., vertical reduction or lengthening and extent of horizontal advancement).

Step 46. Using an oscillating saw with a short fan blade on a long shaft, a vertical groove is made in the midline across and perpendicular to the proposed horizontal osteotomy (Fig. 15-33, *A*). This will help to maintain vertical orientation after the osteotomy and before fixation.

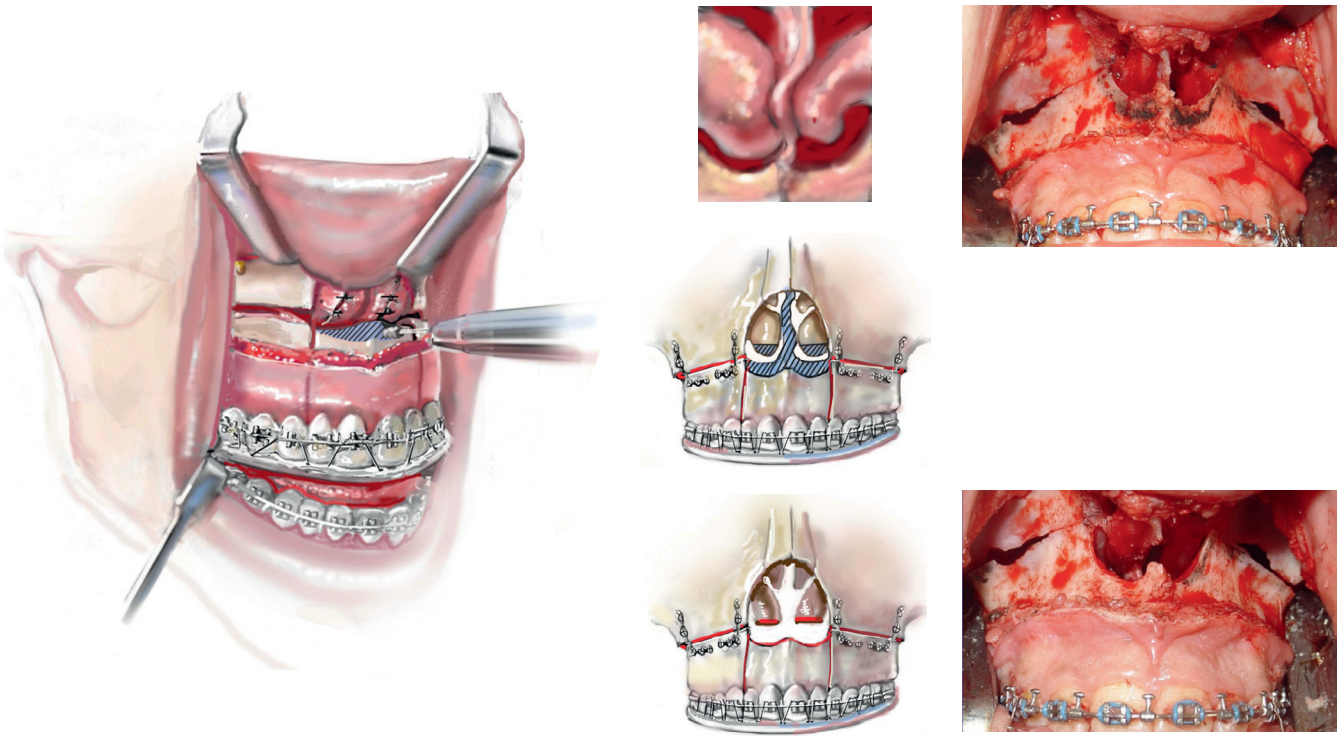
Step 47. A drill hole is placed in the midline within the distal chin (Fig. 15-33, *B*). Later, a screw (1.7 mm in diameter and 8 mm in length) will be partially inserted. The screw is not placed in the distal chin until the osteotomy is completed. It will then be held with a wire twister and used as a retractor and a holder to facilitate the repositioning and orientation of the distal chin unit.

Step 48. The oblique osteotomy of the chin is initiated in the central portion using an oscillating saw with a wide, fan blade on a short shaft (Fig. 15-34). The use of this saw and blade helps to maintain orientation and limit a cant in the osteotomy.

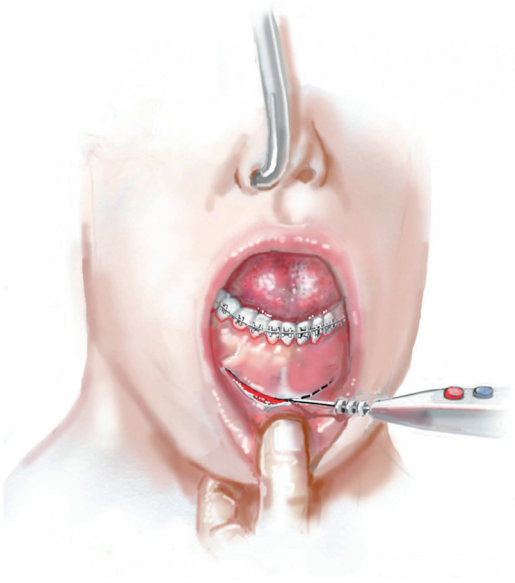
Step 49. The reciprocating saw with a short blade and then with a longer blade is used to complete the lateral aspects of the osteotomy and to go through the



• **Figure 15-29** Step 41.



• **Figure 15-30** Step 42.



• **Figure 15-31** Step 43.

depth of bone on each side (Fig. 15-35). An osteotome may be inserted with a twisting motion to complete the osteotomy separation.

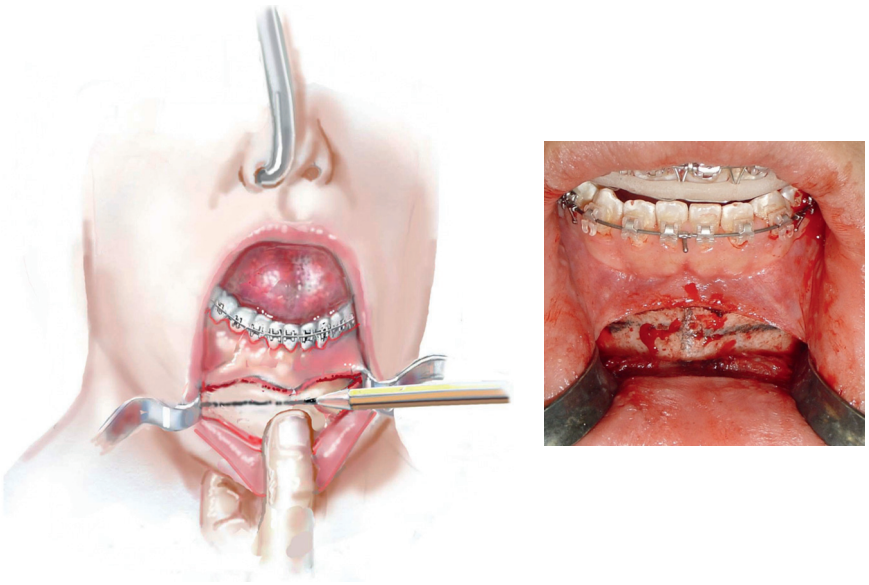
Step 50. When vertical shortening of the chin is planned, there are two options.

A. If only limited shortening is required in combination with horizontal advancement, it may be preferable to use a rotary drill with a watermelon bur to remove bone height at the osteotomy line.

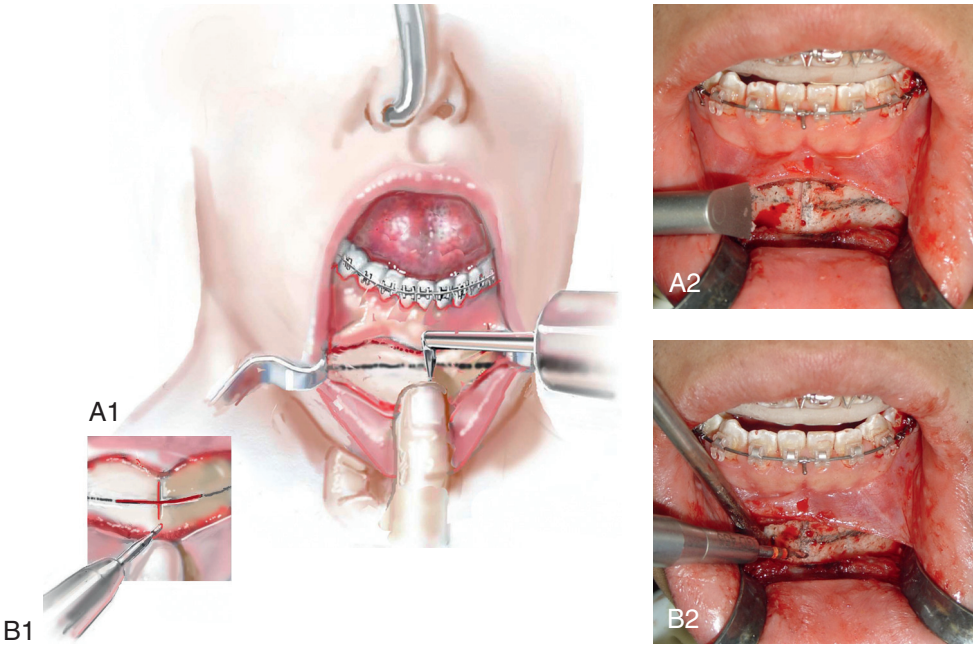
B. If a more significant vertical reduction is planned, a second parallel osteotomy for ostectomy is completed through the proximal chin (below the dental roots) using a reciprocating saw with a long straight blade. Any lateral irregularities are also removed using a rotary drill with a watermelon bur. This is to limit postoperative palpable or visible step-offs.

Step 51. The distal chin is held in the desired position by the assistant with the use of the wire twister secured to the positioning screw. The surgeon custom contours each titanium plate across the osteotomy site and then secures each plate with screws (1.7 mm in diameter and 4 mm in length). Typically, either a three- or four-hole straight plate is contoured with the ends placed on either side of the osteotomy. The superior screw is usually placed in between the lateral incisor and the canine on each side. With the chin secured in its new location, the positioning screw is removed (Fig. 15-36, *A* and *B*).

Step 52. If significant vertical lengthening is carried out, an interpositional graft (i.e., autograft, allograft, or block hydroxyapatite) is crafted and placed in the gap (Fig. 15-37). The graft fills the central gap in between the fixation plates. I do not find it necessary to place graft in the lateral aspect of the gaps.



• **Figure 15-32** Step 45.



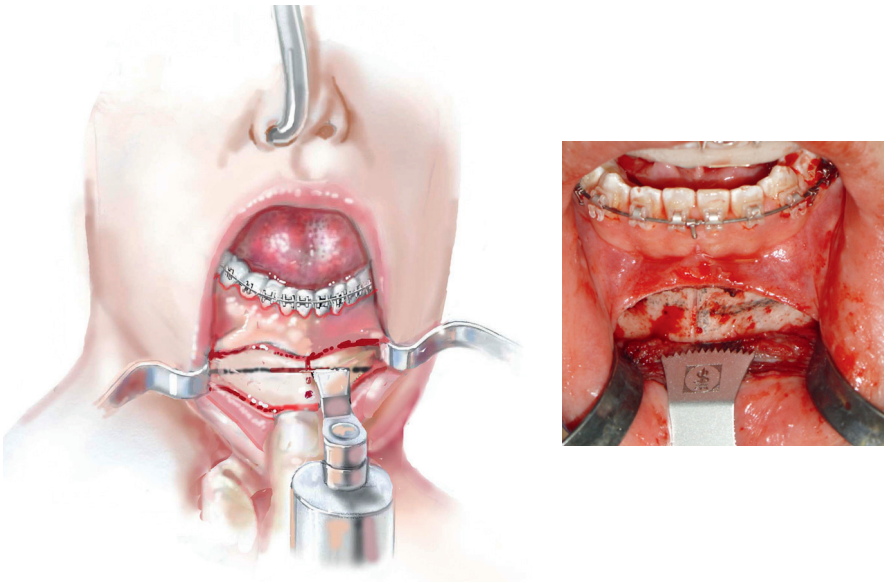
• **Figure 15-33** Steps 46 and 47.

An additional plate with screws is generally placed vertically in the midline across the osteotomy site directly over the graft (see Chapter 18).

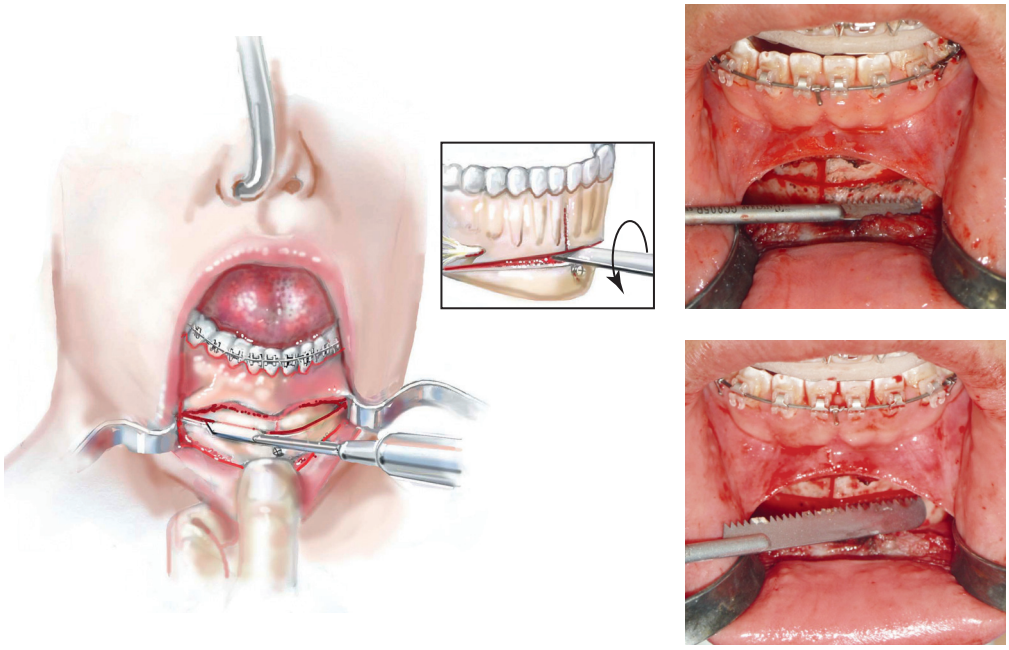
Sagittal Split Ramus Osteotomies: Continued (Video 6:12 and 7:11)

Step 53. Attention is returned to one side of the ramus of the mandible. The previously placed packs are removed and retractors (i.e., tongue, inferior border at buccal extension, toed-in Langenbeck at anterior ramus to retract the cheek, and medium malleable to expose the medial cut) are placed for sufficient exposure to complete the sagittal splitting of the ramus of the mandible.

Step 54. Initially, fine osteotomes (i.e., 5 mm and 7 mm in width) are used with a mallet to confirm that all cortical cuts are complete (Fig. 15-38). When twisting the chisels, a degree of movement should be visualized along the vertical cut down to the inferior border. Care is taken to avoid injury to the inferior alveolar nerve, which is located superficial to the cortex along the inferior aspect of the buccal shelf extension.



• **Figure 15-34** Step 48.

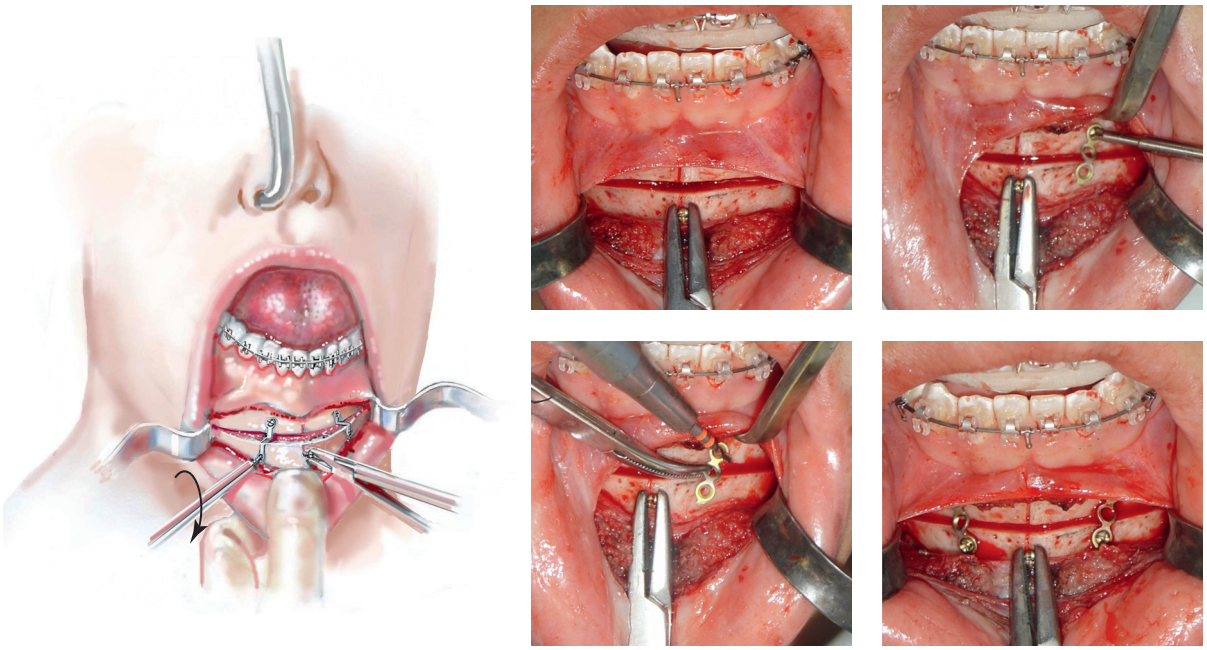


• **Figure 15-35** Step 49.

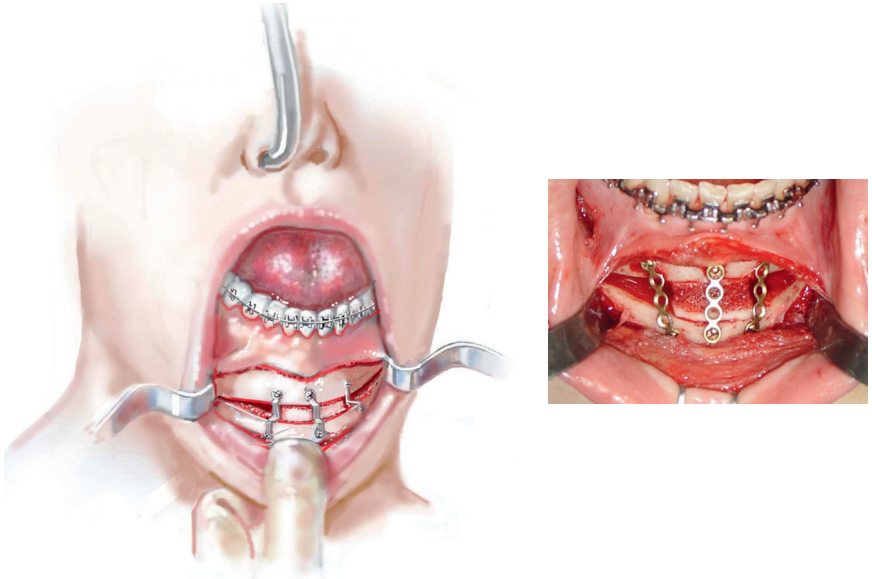
Step 55. A larger osteotome (10 mm in width) is then placed deep into the medullary cavity near the second molar of the mandible. A sagittal split spreader forceps is placed deep into the medullary cavity (i.e., more distal) in the buccal extension region (Fig. 15-39). After both of these are in place, a simultaneous twisting and spreading motion is employed to complete the separation. During separation, the neurovascular bundle is visualized, and the correct separation of the condyle (retained to the proximal segment) is confirmed.

Step 56. With the split complete, further freeing of the neurovascular bundle from the proximal segment is sometimes desirable. A thin periosteal elevator may be used to gently tease the neurovascular bundle free from the proximal segment. A rotary drill with a watermelon bur may also be used to release the neurovascular bundle from the proximal segment.

NOTE: It is not usually necessary to completely free the nerve from the proximal segment. Caution is warranted, because a degree of contusion to the neurovascular bundle will occur when doing so.



• **Figure 15-36** Step 51.



• **Figure 15-37** Step 52.

Step 57. A curved Kocher clamp is placed on the distal aspect of the proximal segment. The clamp is used as a handle to apply force and to ensure the complete separation and freedom of motion of the proximal and distal segments (i.e., soft-tissue release).

Step 58. The identical sagittal splitting of the ramus of the mandible is completed on the contralateral side; see Steps 51 through 57.

Removal of Impacted Mandibular Wisdom Teeth (Video 6:12)

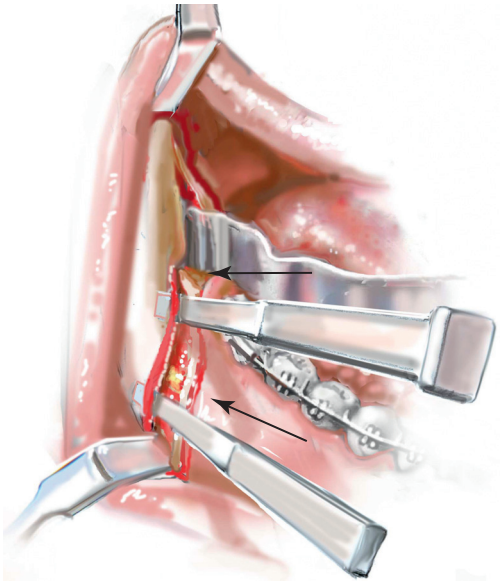
Step 59. If present, each bony impacted mandibular wisdom tooth located within the distal segment is removed with a dental elevator (Fig. 15-40). It may be helpful to use a rotary drill with a tapered fissure bur to remove bone adjacent to the tooth. Sectioning the tooth may be required to facilitate

the atraumatic removal of the tooth. This will minimize the chance for an uncontrolled fracture of the lingual plate.

Sagittal Split Ramus Osteotomies: Continued
(Video 6: 12-15 and 7: 11-14)

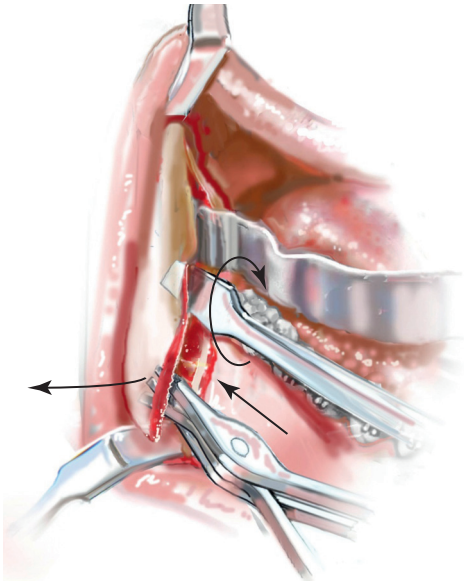
Step 60. The distal mandible is placed into occlusion through the prefabricated final splint, which has already been secured to the maxilla. The jaws are wired together with 26-gauge wire loops placed around the orthodontic interdental hooks (Fig. 15-41).

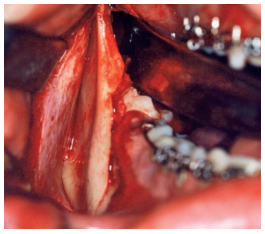
Step 61. Attention is turned to the proximal segment of the mandible on one side. The proximal segment is seated with the condyle in the terminal hinge position. This is accomplished with the placement of a fine curved hemostat to the edge of the buccal extension. The condyle will then rest in a superior and anterior position within the glenoid fossa (i.e., the same position that it was in when capturing centric relation in the office setting). Any interferences that prevent sufficient passive bone contact of the proximal and distal segments along the osteotomy site are managed using a rotary drill with a watermelon bur (Fig. 15-42). If the mandible is set back, an appropriate section of bone is also removed from the distal aspect of the proximal segment (i.e., the buccal shelf) to prevent any cortex overlap. When setting the mandible back, the removal of bone interferences from the lingual plate of the distal segment is also generally required. These tasks are accomplished using either a rotary drill with a watermelon bur or a reciprocating saw with a short, straight blade.

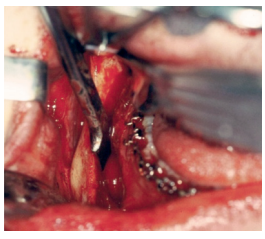


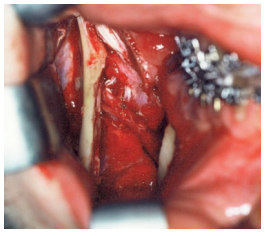
• **Figure 15-38** Step 54.

NOTE: The hemostat is not used to clamp the proximal and distal segments together. Gentle superior and posterior force is applied to seat the condyle in the terminal hinge position.



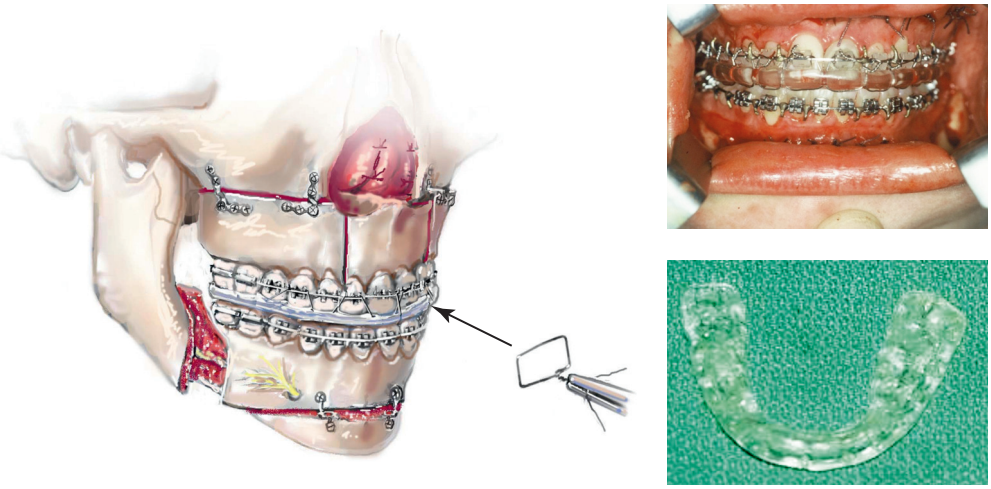




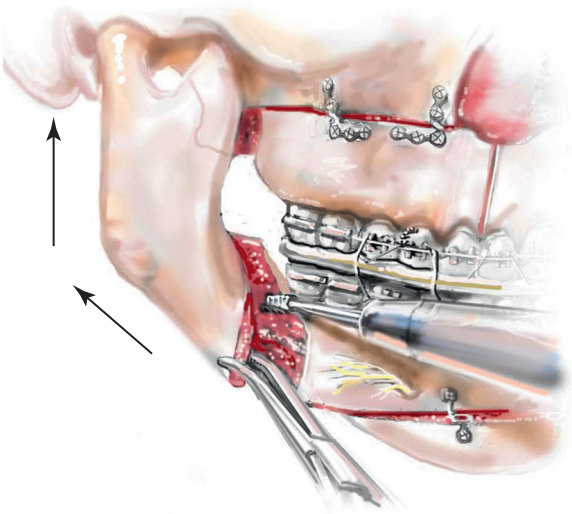


• **Figure 15-39** Step 55.

• **Figure 15-40** Step 59.



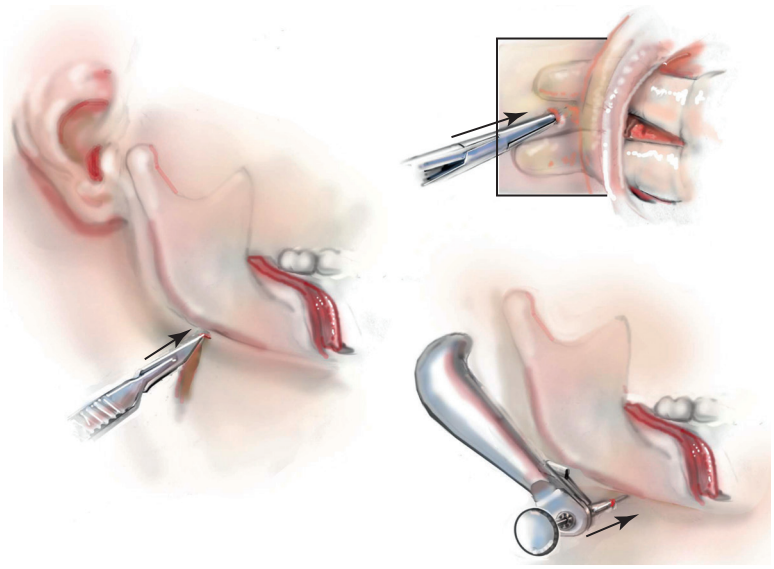
• **Figure 15-41** Step 60.



• **Figure 15-42** Step 61.

Step 62. A 4-mm lateral neck incision (just below inferior border of the mandible) is made through the skin for trocar insertion (Fig. 15-43, *A* through *C*). The location of the incision is based on the best position of the trocar for ideal bicortical screw placement. With the use of a straight hemostat, blunt dissection through the skin incision is accomplished to achieve intraoral exposure. The trocar is then introduced, and the cheek retractor component of the trochar is placed to improve visualization.

Step 63. The proximal segment is seated with the condyle in the terminal hinge position. This is accomplished via the placement of a fine curved hemostat to the edge of the buccal extension. (Note that the hemostat is not used to clamp the proximal and distal segments together.) Gentle superior and posterior force is applied to seat the condyle in the

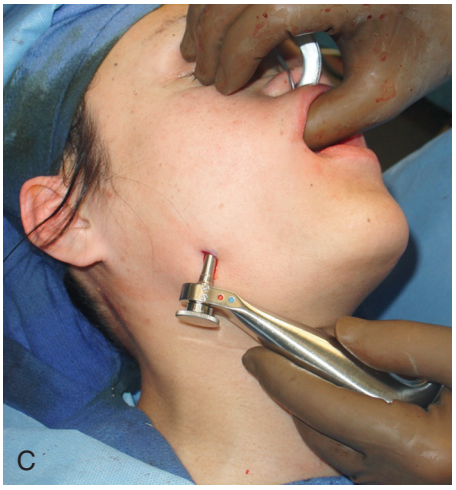


A

B

4-mm skin incision

Insertion of trocar



C

Trocar inserted

Trocar cheek retractor in place

• **Figure 15-43** Step 62.

terminal hinge position. The condyle will then rest in a superior and anterior position within the glenoid fossa (i.e., the same position that it was in when capturing centric relation in the office setting). Three bicortical titanium screws (2.3 mm in diameter and 14 mm to 16 mm in length) are generally sufficient to passively secure the proximal and distal segments together (Fig. 15-44, *A* through *C*). The bicortical screws are placed in locations where bone contact is the best. A fourth screw is sometimes placed. Stability is further improved when the screws are positioned as far from each other as possible. Plates with unicortical screws are occasionally preferred to bicortical screw fixation.

Step 64. Attention is turned to the contralateral side, and identical procedures are carried out; see Steps 60 through 63.

Step 65. The jaws are then unwired. With the application of posterior and superior vectored force to the anterior mandible, the condyles are seated in the terminal hinge position. The mandible is then rotated (up and down) to check that the occlusion is even and passive into the splint (Fig. 15-45). If not, the bicortical fixation screws are removed, and the process is repeated; see Steps 59 through 63.

Wound Closure (Video 6: 16 and 7: 15)

The anesthesiologist is asked to discontinue the deliberate hypotensive anesthesia before wound closure. This should unmask any significant bleeding vessels.

Step 66. The maxillary, mandibular, and chin vestibular wounds are irrigated, suctioned, and checked for hemostasis. The wounds are then closed with interrupted suture (3-0 Vicryl and 3-0 chromic).

A. The mandibular vestibular wounds are generally closed in one layer with interrupted suture (3-0 Vicryl). Running and locking (3-0 chromic) suture may be substituted (Fig. 15-46, *A*). A watertight closure is important to prevent dehiscence followed by increased risk of infection.

B. The maxillary wound is generally closed with running and locking suture (3-0 chromic) (Fig. 15-46, *B*). The risk of dehiscence or infection is low.

C. The wound of the chin is closed in two layers (i.e., muscle and mucosa). Three to five interrupted buried sutures (3-0 Vicryl) are placed for muscle layer closure. Locking and running sutures (3-0 chromic) are used for the closure of the mucosa layer (Fig. 15-46, *C*). A two-layer closure is essential to limit dehiscence and to prevent chin ptosis.

D. The trocar (skin) wounds are closed with two interrupted sutures (6-0 nylon).

Step 67. The mouth is irrigated and suctioned, and the throat pack is removed. An orogastric tube is placed to drain the stomach and then removed. Interdental elastics are applied to secure the occlusion.

Anterior Neck Soft-Tissue Procedures (Video 7:16)

Step 68. If anterior neck soft-tissue management is planned, it is carried out at this stage. This may include cervical flap elevation, supra-platysma and sub-platysma defatting, and vertical platysma muscle plication (see Chapter 40). Additional prepping with povidone–iodine (Betadine) solution is carried out, and a sterile drape is placed over the standard drapes that are already in place. Sterile instruments and a fresh gown and gloves are used. Injection with tumescent solution is completed in the supra-platysma plane.

A. A 3-cm submental incision is made within or just caudal to a natural submental crease.

B. Two double skin hooks are placed (i.e., one on either side of the incision) to provide tension on the flaps.

C. If the separation of the cervical skin from the underlying platysma muscle is planned, it is accomplished with a blunt-tipped scissors. The cervical skin flap elevation off of the platysma muscle may continue laterally over the sternocleidomastoid muscles inferiorly to the thyroid cartilage and superiorly to the inferior border of the mandible.

D. A cannula (no. #7 plastic curved) is used to suction the fat above and in between the platysma muscles.

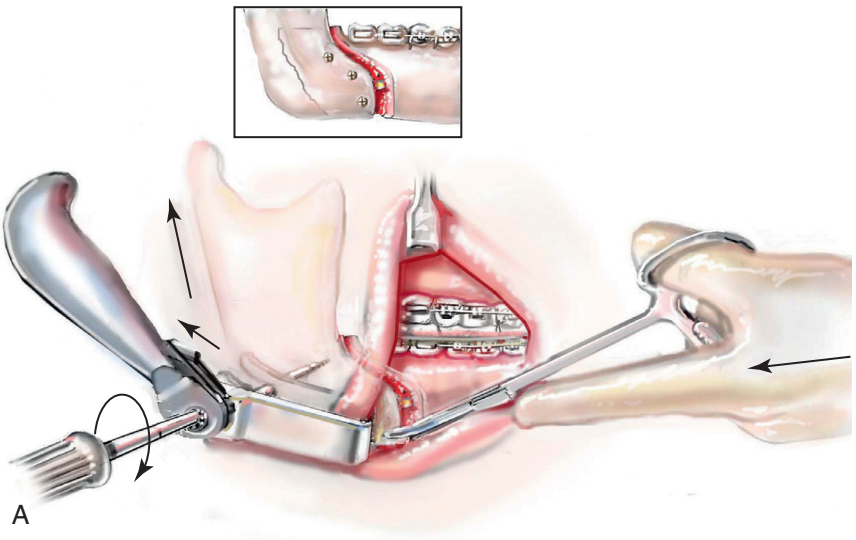
E. Plication of the platysma muscle in the midline (vertically) from above the thyroid cartilage to just below the chin may also be carried out with interrupted suture ties (3-0 Vicryl).

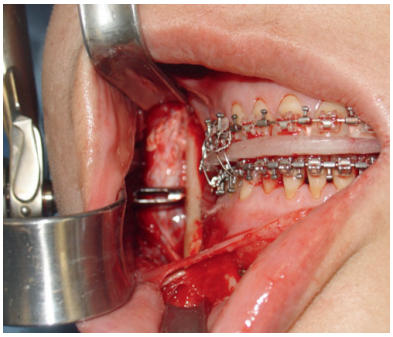
F. After confirming satisfactory hemostasis, the submental skin wound is closed in two layers: dermal (5-0 Vicryl) and skin (6-0 nylon).

G. A light pressure dressing (Jobst type) is generally applied to the neck. In general, I do not find it necessary or useful to place a drain.

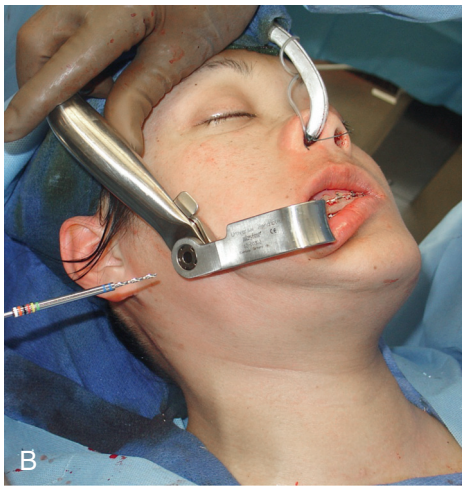
Emergence from Anesthesia

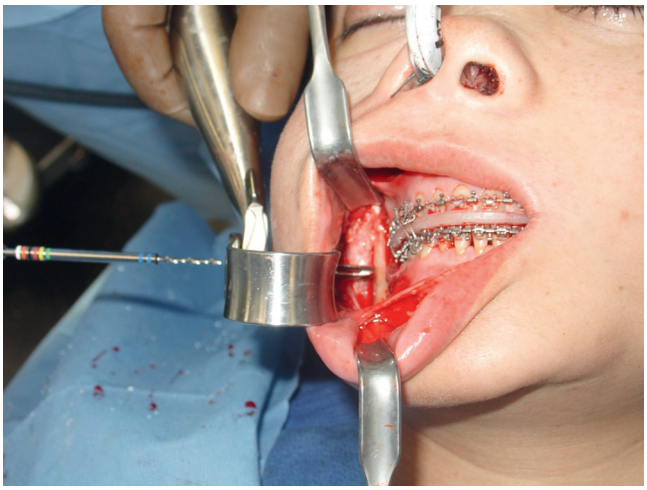
Step 69. The corneal shields or temporary tarsorrhaphies, if used, are removed. The sutures used to secure the endotracheal tube to the scalp and the septum of the nose are released. When the appropriate





Intraoral view with trocar in place





Power drill (2.3-mm bit) inserted through trocar

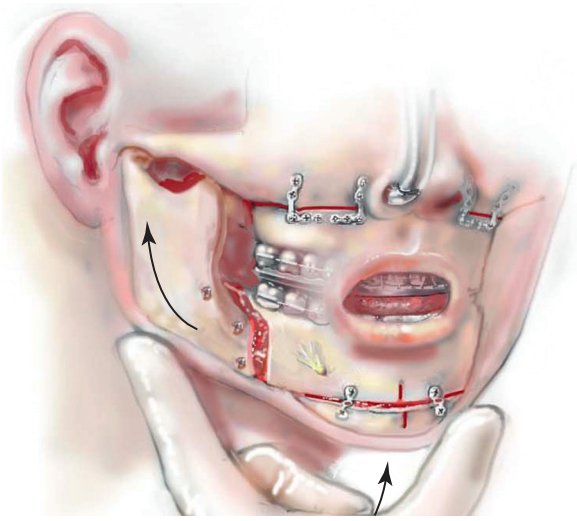
• **Figure 15-44** Step 63.

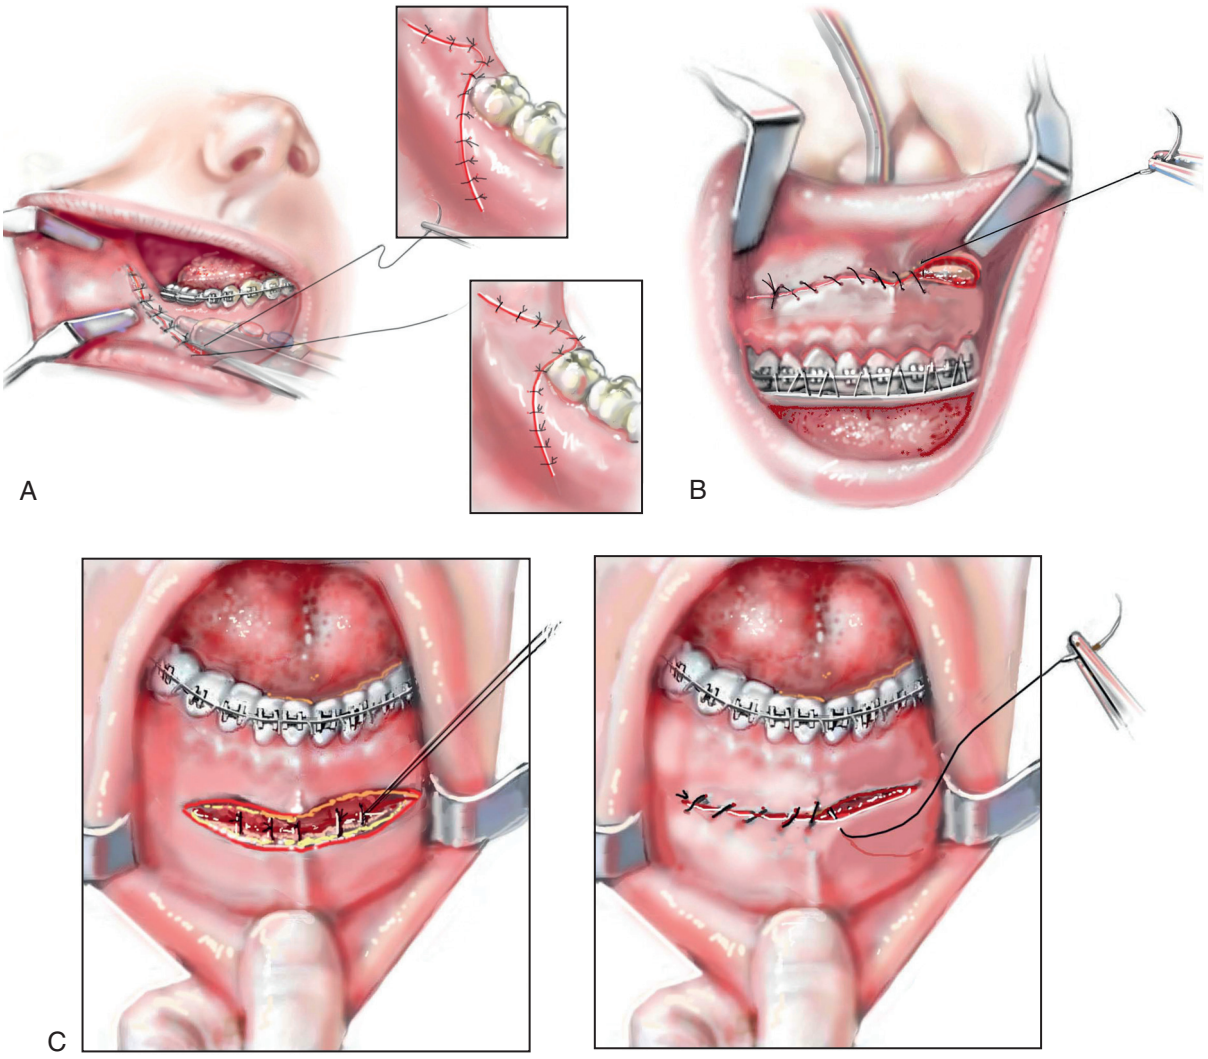


• **Figure 15-45** Step 65.

physiologic parameters are met, the patient is generally extubated in the operating room and then taken to the recovery room breathing spontaneously. If any airway need arises, the interarch elastics are removed without concern (see Chapter 11).

Conclusions

The surgical management of dentofacial deformities has gradually evolved. By understanding the technical details for the safe execution of the maxillary (Le Fort I), mandibular (sagittal splitting of the ramus), and chin (osseous genioplasty) osteotomies, each skeletal unit may be precisely and efficiently repositioned (i.e., in three dimensions) during one operation. Other simultaneous adjunctive procedures (i.e., septoplasty; the reduction of the inferior turbinates;



• **Figure 15-46** Step 66, A, B, and C.

the recontouring of the pyriform rims, the nasal base, and the anterior nasal spine; the removal of wisdom teeth; and soft-tissue neck rejuvenation) are routinely performed, when indicated, to improve head and neck function (i.e. occlusion, chewing, speech articulation, swallowing, breathing, and lip closure) and to enhance facial aesthetics. Special circumstances and unusual anatomy may require variations of the techniques described in this chapter. The development of a consistent approach for most routine cases limits morbidity and increases efficiency of care.

Complications Associated with Orthognathic Surgery

JEFFREY C. POSNICK, DMD, MD

- General Considerations
- Risks and Complications Specific to Sagittal Ramus Osteotomy of the Mandible
- Risks and Complications Specific to Le Fort I Osteotomy
- Risks and Complications Specific to Oblique Osteotomy of the Chin
- Conclusions
- Patient Education Materials

General Considerations

No matter how accurate the diagnosis and how meticulous the surgeon, complications will occur after orthognathic procedures.* Alternatively, the relative safety of orthognathic procedures has been confirmed by a number of retrospective reviews.[13,32,84,93,152,223,245,254,315,353] Panula and colleagues reviewed maxillary and mandibular osteotomy patients at their institution (N = 655) and found only one serious complication (intraoperative bleed). A prospective study of Le Fort I operations by Kramer and colleagues (N = 1000) found a 6.4% incidence of complications that ranged from extensive bleeding (1.1%) to sensory loss in the distribution of the infraorbital nerve.[173] A review by Chow and colleagues of a consecutive series of orthognathic patients (N = 1294) documented a relatively high complication rate (9.7%)[61]; this included mostly manageable "postoperative infections" (7.4%), with no serious or rare events recorded. A large series of orthognathic patients (N = 2049) was reviewed by Van de Perre and colleagues[346]; those authors identified one patient death and 44 other patients with either primary or secondary complications.

*References 2, 23, 25-27, 42, 53, 78, 80, 83, 118, 146, 150, 157, 162, 186, 203, 206, 212, 224, 242-244, 246, 252, 262, 266, 314, 322, 328, 334, 335, 341-343, 345, 347, 355, 362-364.

The definition of what constitutes a complication in orthognathic surgery varies between both researchers and clinicians, thereby making interstudy comparison difficult. By understanding the medical history and physical findings of the individual who presents with a dentofacial deformity including 1) an awareness of any associated conditions or malformations 2) the patient's baseline psychosocial health and 3) any head and neck dysfunctions—patient-specific complications can be minimized. A thorough informed consent process should also focus on patient-specific and family-centered issues. The patient's specific risk factors should be presented to the individual and his or her family for consideration before treatment.

Medical Risk Factors

An essential part of risk assessment includes the surgeon's performance of a thorough review of the patient's medical records and the completion of a history and physical examination. A general clearance examination by the patient's pediatrician or general physician and further confirmation of the patient's health through appropriate laboratory testing is also important. The pregnancy testing of females of childbearing age should be performed routinely the morning of surgery.

For middle-aged adults who are considering orthognathic surgery, additional medical risk factors may include cardiovascular disease; obesity or increased body mass index; obstructive sleep apnea; diabetes; pulmonary disease; smoking history; the potential for deep vein thrombosis or pulmonary embolus; and osteoporosis or the use of bisphosphonate treatment (see Chapter 25).[30,50,172] Evaluation by the patient's primary care physician (and, in many cases, by other medical specialists) and appropriate laboratory work (e.g., electrocardiography, chest radiography, chemistries, hematology, thyroid tests, coagulation studies) help to identify areas of concern. The adult patient with an elevated body mass index who is undergoing surgery is at greater than average risk for intraoperative and postoperative complications. The presence of obstructive sleep apnea in the

patient with a jaw deformity should be considered and ruled out (see Chapter 26).

Wound-Healing Risk Factors

Specific patient factors that may impair wound healing include diabetes mellitus, smoking, bisphosphonate treatment for osteoporosis, poor nutritional status, and chronic glucocorticoid exposure. Type II *diabetes mellitus* is frequently a comorbidity of obesity and increased body mass index. Alpha and colleagues documented a 66% incidence of postoperative infections among diabetic patients undergoing maxillary or mandibular osteotomies, despite adequately controlled glucose levels.[9]

The *inhalation of nicotine* via cigarettes affects both pulmonary function and wound healing.[72,75,95,264,137,149,176] Smoking or nicotine ingestion has been shown to delay the chondrogenic phase of bone (osteotomy) healing and to decrease the circulation of surgically elevated flaps, thereby resulting in impaired healing after wound closure. Cigarette smoke contains nicotine, carbon monoxide, and hydrogen cyanide; each of these chemicals has been shown to impair wound healing by producing relative tissue hypoxia. Nicotine is a vasoconstrictor that diminishes tissue oxygenation, predisposes the individual to microvessel thrombosis (i.e., increased platelet adhesion and direct endothelial cell damage), and diminishes cell proliferation and function. Carbon monoxide reduces oxygen-carrying capacity, and hydrogen cyanide inhibits oxidative metabolism and oxygen transport. These consequences of cigarette smoke tissue ischemia are most evident during healing after surgical procedures, when tissue circulation is at risk for interruption (e.g., after microvascular tissue transfer, during the placement of free [non-pedicled] bone grafts). A number of clinical studies have documented increased morbidity in patients who smoke and later undergo head and neck reconstructive and aesthetic procedures. To minimize postoperative wound difficulties and anesthesia-related pulmonary complications, patients should be counseled to refrain from smoking for at least 6 to 8 weeks preoperatively and for 2 to 4 weeks postoperatively. A serum or urine nicotine concentration can be obtained before surgery to confirm patient compliance.

It is known that *bisphosphonate treatment for osteoporosis* can affect osteoclast activity and that it may negatively impact successful bone healing. Current guidelines concerning bisphosphonate treatment continue to evolve and should be followed when planning jaw or dentoalveolar procedures.[1,85,125,198,209,214,215,220-222,248,283,285,292,294,357,367]

Perioperative Airway Risk Factors

Perioperative risk to the airway and its management should be considered during all phases of surgical care, including before nasotracheal intubation, during surgery, at the time of extubation, and soon after extubation (Fig. 16-1).[53,61,76,170,175,250] The basic clinical preoperative airway assessment should include 1) measurements of mandibular range of motion (i.e., vertical opening and protrusion); neck mobility 2) Mallampati classification 3) the ratio of the patient's height to the thyromental distance 4) neck circumference and 5) body mass index. A Mallampati classification of III or IV or a ratio of height to thyromental distance of more than 23.5 is a strong indicator of a difficult

• **Figure 16-1** Perioperative risk to the airway and its management should be considered during all phases of orthognathic surgery, including before nasotracheal intubation, during surgery, at the time of extubation, and soon after extubation. Individuals who are scheduled for orthognathic surgery and who are recognized to be at high risk for airway compromise should be reviewed in advance with the anesthesia team to arrange for special needs. Three patient examples in which these issues came into play are shown, including an adult with Noonan syndrome, a teenage girl with Treacher Collins syndrome, and a teenager with Klippel–Feil anomaly. Each of these patients also has the potential for cervical spine anomalies with limited neck range of motion. The risk for spinal cord injury should also be evaluated before orthognathic surgery.

airway with conventional direct laryngoscopy. A *neck circumference* of more than 17 inches in men is a risk factor for obstructive sleep apnea. Individuals who are scheduled to undergo orthognathic surgery may have special medical risk factors that include baseline malformations or syndromes and associated abnormalities that carry the potential for difficult airway control (see Chapter 11). In the high-risk patient, advance discussion with the anesthesia team to arrange for an anesthesiologist who is experienced with difficult away management and who is skilled with awake fiber-optic intubation may be indicated (see Fig. 16-1) (Video 5). After the nasotracheal tube is in place, the surgeon secures it and assists with its management during the operation (see Chapter 15). Complications associated with endotracheal tubes that are placed for orthognathic procedures have included herniation of the airway tube cuff leading to occlusion of the tube lumen; inadvertent surgical sectioning of the endotracheal tube; and the occurrence of contact granuloma of the vocal cords.[62,249] Acute intraoperative or postoperative pulmonary edema, postoperative apnea, pneumomediastinum, and pneumothorax have all been reported as complications associated with anesthesia (see Chapter 11).[14,33,34,56,91,117,122,153,217,233,245,259,318,321]

Malignant hyperpyrexia involves an abnormality of muscle metabolism of genetic origin that manifests as widespread skeletal muscle contraction, hypercatabolism, and hyperthermia upon exposure to volatile anesthetic agents or succinylcholine.[192,223,365] It is a serious condition that requires prompt diagnosis and aggressive management. It may occur during an orthognathic procedure with a typical initial intraoperative presentation of tachycardia and noticeably warm skin.

Decisions about the timing of extubation after surgery should be made by clinicians on the basis of extubation criteria and patient-specific risk factors.[159,376] In general, the surgeon is present at the time of extubation in case either *emergency tracheostomy* or reintubation is required. Our preference is to extubate the patient in the operating room when feasible but only when specific parameters are met. For the patient with an ongoing difficult airway, a more delayed approach to extubation maybe taken. The risk of inadequate ventilation after extubation is highest when preextubation parameters are not adequately met and when excess sedation remains (see Chapter 11).

Spontaneous leg compartment syndrome has been reported as a complication after orthognathic surgery.[204] The occurrence is thought to be the result of a drug interaction between anesthetic or postoperative medications or the effect of antidepressive drugs that are superimposed on chronic mild exercise-induced compartment syndrome.

Death is recognized as an exceedingly rare complication related to orthognathic procedures. Of the numerous large case series published, only one death has been described; this was reported by Van de Perre and colleagues from a series of 2049 patients.[210] It occurred in a 17-year-old male patient who was described as being slightly mentally challenged and who underwent bimaxillary osteotomies. Six hours postoperatively, a cardiac arrest occurred, and attempts to resuscitate the patient failed. The cause was thought to be preexisting cardiomyopathy. A death was also reported by Waack and colleagues as part of a limited series of 63 consecutive Le Fort I osteotomies.[216] The death occurred in a healthy 15-year-old female patient on the first postoperative day as a result of unknown causes.

Cervical Spine Risk Factors

As part of the presurgical assessment, the evaluation of the patient's cervical spine is essential. *Congenital malformations*, *previous trauma,* and *arthritis* are occasional etiologies of cervical spine problems in the orthognathic patient. Patients with specific syndromes (e.g., Klippel–Feil anomaly, hemifacial microsomia, Treacher Collins syndrome, Apert syndrome) are at higher risk for a cervical spine malformation that may be undiagnosed at presentation to the orthognathic surgeon (see Fig. 16-1). Referral for evaluation by an orthopedic spine surgeon, a neurosurgeon and a geneticist as well as appropriate radiographic studies (e.g., magnetic resonance imaging, computed tomography) are carried out when indicated. Controlled positioning with limited flexion, extension, and rotation at the time of intubation, intraoperatively, and during recovery may be required. In some cases, *intraoperative neuro-monitoring* (e.g., motor and sensory) is useful to confirm minimal spinal compression during surgery.

Psychosocial Risk Factors

To minimize patient and family disappointment after surgery, an informal (or, in some cases, a more rigorous) *psychosocial assessment* is conducted.[24,36,73,81,167,304,317] All parties involved must accept the risks and limitations of the planned surgical procedures. Unfortunately, neither the preoperative psychosocial assessment nor the individual's biologic wound-healing ability is completely predictable. A small percentage of patients will perceive an unfavorable surgical outcome, even when the clinicians feel that the results are at least satisfactory. Others will not accept a complication, even though the risks were fully explained in advance and all precautions were taken.

Body dysmorphic disorder is a medical condition that can be difficult to recognize before surgery but that will routinely result in postoperative patient dissatisfaction. It is estimated that 7% to 15% of individuals who pursue cosmetic surgery have body dysmorphic disorder (see Chapter 7).

Comprehensive Dental Rehabilitation Needs

Recognizing when a patient who is seeking orthognathic surgery has dental needs that go beyond standard orthodontics is essential to the achievement of an optimal outcome (see Chapter 5). If *complex dental restorations* and *periodontal management* are necessary, then planning should

coordinate care for these needs at the beginning of treatment (see Chapter 6). This is especially true for the individual with a cleft lip and palate or a craniofacial syndrome (see Chapters 28 through 34). It is also true for the adult who has suffered dental and periodontal sequelae from an uncorrected dentofacial deformity or previous treatment (e.g., orthodontics, restorative care) (see Chapter 25).

Functional Assessment of Head and Neck Structures

The orthognathic surgeon should evaluate the patient's baseline head and neck functions, including speech, swallowing, mastication, neck and mandibular range of motion, breathing, hearing, vision, cognition, and psychosocial competence. Any of these functions may be negatively affected by the presenting maxillofacial deformity or malformation and influenced (either favorably or unfavorably) by the treatment being contemplated.[94,113,139,163,228,232,311,313,320,377] A candid discussion with the patient and the family about the potential impact of the planned procedures on any of these functions should take place before treatment.

Operating Room Team Preparation

Limiting risks and complications requires an informed patient and family, coordinated collaborative comprehensive clinical care, an experienced and focused surgeon, meticulous planning, a dedicated operating room team, effective postoperative hospital care, and appropriate outpatient management. The *operating room team* includes the surgeon and his or her assistants, the anesthesiologist and his or her assistants, the operating room personnel (e.g., scrub nurse/technician, circulating nurse), and the full complement of sterilized and organized instrumentation (e.g., inventory, sanitation and sterilization personnel). The *instrumentation* includes power saws and drills, with their associated bits and blades; handheld instruments; and fixation hardware such as plates and screws. Specific *medications, sutures,* and *dressing materials* are also required. The confirmation of the prepared operating room team, equipment, instrumentation, and medications should be undertaken before the patient enters the operating room. The anesthesiologist and the surgeon should discuss the patient's airway and his or her intraoperative and postoperative needs before entering the operating room (see Chapter 11). After the equipment, instrumentation, and medications are set up and checked and the team is briefed, the patient may enter the operating room with the best opportunity for success.

Temporomandibular Disorders

The effects of orthognathic surgery on temporomandibular joint function are often specific to the patient and cannot be fully predicted.[11,82,138,139,156,247] Many clinical studies report improvement in temporomandibular joint symptoms in a majority of patients after successful orthodontics and orthognathic surgery, whereas some of the study patients show deterioration. The favorable effects of orthognathic surgery for patients with preexisting temporomandibular joint symptoms may result from the improved occlusion, the corrected facial height and horizontal projection, and the reduced emotional stress (or the placebo effect). Varied degrees of documented radiographic condylar remodeling after orthodontics and orthognathic surgery have been reported in some patients. Interestingly, TMJ radiographic findings do not necessarily correlate with symptomatic temporomandibular disorders (see Chapters 9 and 37).

Management of Third Molars

Historically, the presence of impacted third molars during a sagittal ramus osteotomy (SRO) of the mandible has been presumed to be associated with increased complications including the following: 1) a higher incidence of "bad splits" 2) a higher incidence of infection 3) issues with the placement of fixation (i.e., osteotomy stabilization) and 4) difficulties maintaining the integrity of the inferior alveolar nerve (IAN). It is for these reasons that, in the past, the removal of impacted mandibular third molars 6 to 12 months before an SRO was routinely recommended. However, the arguments against this approach are that this subjects the patient to two surgeries, two anesthetic treatments, and two recovery periods rather than just one and that this staged approach may in fact increase rather than decrease the previously mentioned complications.

Clinical studies have now documented no increased risk of unfavorable or so-called "bad splits" when SROs are performed in patients with impacted third molars as compared with those without third molars.[90,218,268,276,348] Doucet and colleagues laid this argument to rest with their prospective cohort study that looked at the effects of the presence or absence of third molars during SRO on 1) the frequency of unfavorable fractures 2) the degree of entrapment of the IAN in the proximal segment and 3) the procedural time required to move the teeth.[89] The study included patients who were scheduled to undergo SRO to correct a dentofacial deformity. Study patients were divided into two subgroups: Group I was made up of those with an impacted mandibular wisdom tooth at the time of SRO (n = 331; mean age, 19.6 years); Group II included those without a mandibular wisdom tooth at the time of SRO (n = 346; mean age, 30.4 years). The overall incidence of unfavorable fractures was 3.1% (21 out of 677), with frequencies of 2.4% (8 out of 331) in Group I and 3.8% (13 out of 346) in Group II. Interestingly, the rate of IAN entrapment in

NOTE: When the removal of impacted mandibular third molars is recommended to the patient for long-term dental health, it is generally this author's preference to do so at the time of orthognathic surgery (Fig. 16-2, *A*).

the proximal segment was significantly lower in Group I (37.2%) than in Group II (46.5%). The removal of third molars at the time of SRO increased procedural time by only 1.7 minutes.

As documented in published studies, this author has not experienced increased levels of complications (e.g., infection, bad split, inability to place fixation, increased incidence of inferior alveolar paresthesia) by doing so.

Exceptions to the routine removal of impacted wisdom teeth at the time of orthognathic surgery may include a severely hypoplastic mandible that requires extensive advancement (i.e., in certain patients with hemifacial microsomia or Treacher Collins syndrome). In such cases, maximal ramus region bone stock is needed for osteotomy stabilization and healing. For those few patients, the preoperative removal of the wisdom teeth followed by adequate time for sufficient bone fill (i.e., 12 months) may be preferred.

When the removal of erupted or partially erupted mandibular wisdom teeth is carried out at the time of SRO, the standard vestibular incision for SRO is altered to achieve access to the erupted wisdom teeth and then for watertight wound closure (Fig. 16-2, *B*) (also see Chapter 15). *In review, when considering evidence-based medicine, the routine practice of the removal of wisdom teeth before SRO can no longer be justified.*

When removing impacted maxillary wisdom teeth, access through the floor of the antrum after down-fracture at the time of Le Fort I osteotomy represents this author's usual approach (Fig. 16-2, *C*). The exception is when carrying out segmental osteotomies in a cleft maxilla in conjunction with extensive horizontal advancement of the lesser segment. In these cases, the removal of the wisdom tooth in the lesser segment may significantly diminish bone volume with potential compromise of stabilization and healing.

The removal of an erupted or partially erupted maxillary wisdom tooth is completed through the gingival opening before down-fracture. When this is done, minimal flap elevation is essential so as not to compromise maxillary perfusion after down-fracture.

Fixation Considerations

Need to Remove Plates and Screws

Metal plates and screws have been used to stabilize fractures and osteotomies in the maxillofacial region for more than 40 years.[8,9,12,39,46,47,104,131,151,164,225,281,336] The metals that were initially used were stainless steel and vitalium; these were followed by titanium and its alloys.

There is both laboratory and clinical evidence of the tissue compatibility and the high corrosion resistance of titanium and its alloys in the human body. In 1991, the Strasbourg Osteosynthesis Research Group recommended that "the removal of a non-functional plate is desirable provided that the procedure does not cause undue risk to the patient."[32A,355A] During earlier years, those who were advocating the routine removal of fixation devices after stable bone union felt that the implant had significant potential to cause problems, so its removal was considered preventative. Today, clinicians agree that the medical risk and financial costs incurred by the routine removal of asymptomatic fixation hardware cannot be justified. It is currently standard practice to remove fixation plates and screws only when clinically indicated.

Becelli and colleagues completed a retrospective analysis of complications of bicortical screws used for sagittal split ramus osteotomy (SSRO) fixation.[22] The authors reviewed a consecutive series of patients (N = 241) who were undergoing sagittal ramus osteotomies (N = 482) for skeletal Class III deformities. Complications related to bicortical titanium screws were observed at 3% of the osteotomy sites (Fig. 16-3). The hardware was eventually removed in these patients (15 out of 482), without long-term consequences.

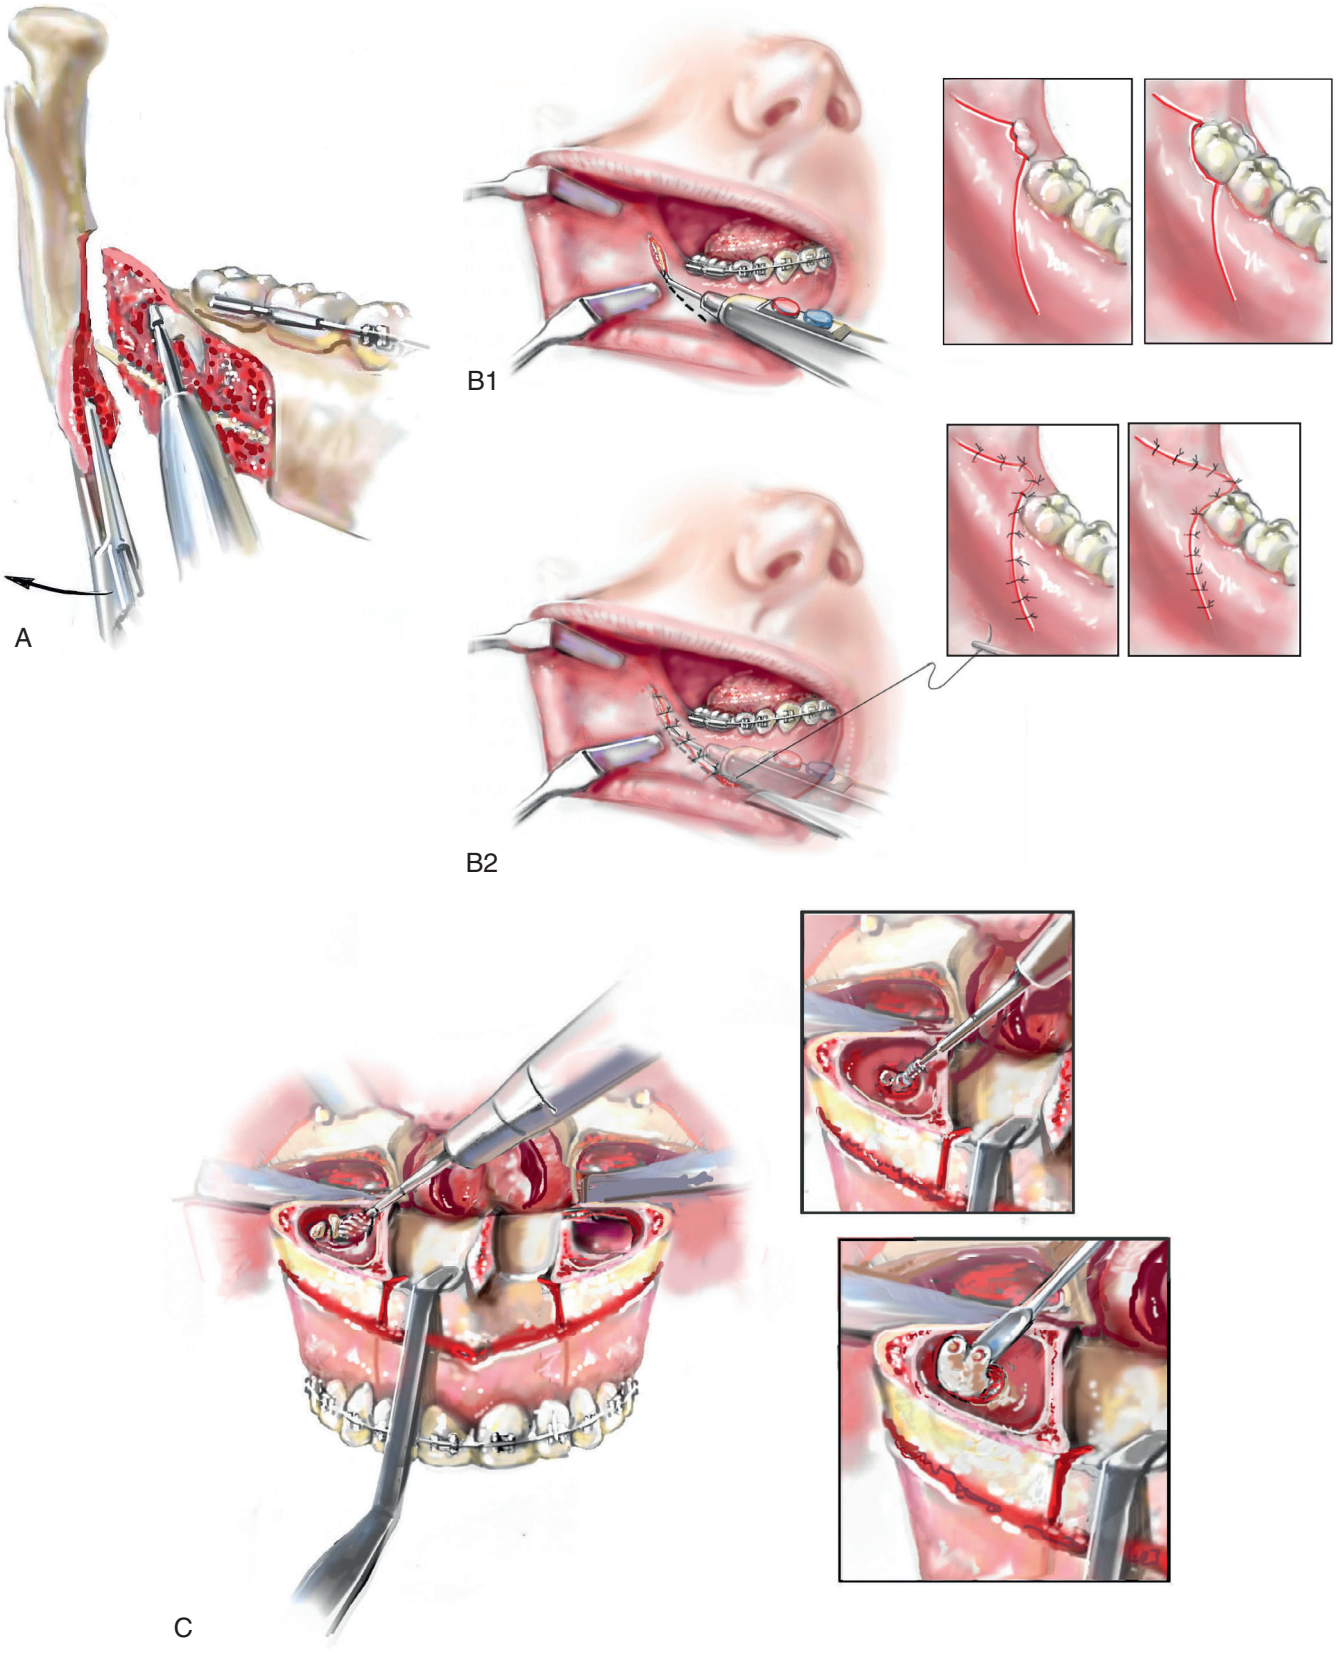
NOTE: In this author's personal series of orthognathic procedures from more than 27 years of clinical practice, the need to or a request by the patient to remove a plate or screw after healing has involved less than 2% of individuals (Fig. 16-3).

The indications for removal fall into the following categories: 1) a palpable and bothersome piriform aperture plate or screw at the Le Fort I osteotomy site when the skin is compressed against it with a finger; 2) a palpable and bothersome zygomatic buttress plate when a food bolus compresses against it while chewing; 3) an exposed bicortical screw head in the labial vestibule at the SSRO site; 4) a screw in close contact with a dental root that is symptomatic; and 5) a bicortical screw that extends through the lingual cortex of the ramus and that causes discomfort or concern, either during movement of the tongue or upon contact with food during swallowing. Under these circumstances, the elective removal of the involved plate or screw is carried out after osteotomy healing has occurred (i.e., preferably 6 to 12 months after surgery).

Use of Titanium versus Resorbable Fixation

The use of self-reinforced biodegradable bone plates and screws has been advocated for use in orthognathic surgery by a limited number of surgeons throughout the world.[92,96,127,130,155,165,178,297,325,344,345] Although this type of fixation is appealing in theory, a greater incidence of postoperative complications has been found with resorbable fixation devices as compared with titanium. Furthermore, no advantages in the achievement of improved skeletal stability have been documented with the use of biodegradable hardware.

Turvey and colleagues reported about 70 patients who were undergoing 194 osteotomies of the maxilla or the mandible and who were stabilized with self-reinforced polylactate bone plates or screws of similar size and configuration to those of titanium systems.[344] The placement of the devices was accomplished transorally and transfacially in a way that was consistent with the osteotomy location. Maxillomandibular elastics were used for each patient after



• **Figure 16-2** **A,** Illustration of an impacted mandibular wisdom tooth being removed in conjunction with sagittal ramus osteotomy. **B,** Illustrations of incision options that are used for ramus osteotomy exposure and then for wound closure. The incision used is dependent on wisdom tooth location. **C,** Illustrations of the removal of an impacted maxillary wisdom tooth through the sinus after Le Fort I down-fracture.

• **Figure 16-3** An 18-year-old with a bilateral cleft lip and palate jaw deformity underwent cleft–orthognathic surgery including maxillary Le Fort I osteotomy in three segments and interpositional iliac bone grafting. Healing was uncomplicated, with the achievement of the planned improvements. One year after surgery, the patient returned with a complaint of a painless ridge in the left buccal vestibule of the maxilla. Examination confirmed an exposed titanium plate and screw. There were no associated symptoms or signs of infection. During an office procedure, the exposed plate was sectioned with a wire cutter and removed. Healing was uneventful.

surgery to control the position of the jaws. Three out of the 70 patients (4%) experienced immediate postoperative loosening of the resorbable bone screws. Each of the patients required a return to the operating room for more rigid stabilization at the involved osteotomy site. Although all patients eventually achieved acceptable occlusion, a number of fixation sequelae occurred during the healing phase, including prolonged mobility of the maxilla; sterile abscess requiring debridement; swelling with sterile fistula tract formation; and intranasal inflammation requiring fixation removal at the time of secondary septoplasty. Although the authors demonstrated that biodegradable plates and screws could be used for orthognathic surgery, there was no advantage when this was compared with titanium fixation devices, and the complication rate is increased.

In a second study, Turvey and colleagues reported about 69 patients who were undergoing sagittal split ramus osteotomies for mandibular advancement.[345] Thirty-four of these patients underwent fixation with self-reinforced biodegradable screws, whereas 35 patients underwent fixation with 2-mm titanium screws. Postoperatively, one of the patients with biodegradable screws required a return to the operating room for improved fixation. Again, no advantage could be demonstrated with the use of biodegradable fixation, whereas a degree of diminished levels of stabilization and increased complications were shown to be present.

Ahn and colleagues completed a study to evaluate the complications of resorbable versus nonresorbable plate and screw fixation in orthognathic surgery.[3] Patients were enrolled in the prospective study (N = 272). Titanium plates and screws were used at the osteotomy sites in Group I (N = 152), and resorbable plates and screws were used at the osteotomy sites in Group II (N = 120). In the 152 patients with titanium plates and screws, there was a complication rate of 8.6% (N = 13). Of the 120 patients with resorbable plates and screws, 18.3% (N = 22) developed complications. There was a greater degree of postoperative infections and malocclusions and a trend toward relapse observed in patients with resorbable plate and screw fixation. Three of the patients with resorbable plate and screw fixation required reoperation for residual malocclusion as compared with zero in the titanium group.

Infection Associated with Orthognathic Procedures

Infection after orthognathic surgery is considered by most to be uncommon. However, a review of the literature indicates a wide range in the reported incidence of this complication.* A critical review of these studies provides insight into the true incidence of infection, clinical pitfalls to consider, and methods to use to best limit these sequelae.

All transoral wounds must be considered "clean-contaminated wounds," with an anticipated theoretical infection rate of as high as 15%.[352] It is said that this incidence of infection in a clean-contaminated site can be reduced to as low as 1% with good surgical technique and the appropriate use of prophylactic antibiotics. The question remains of how to best provide this type of antibiotic coverage for the orthognathic surgery patient. According to the infectious disease literature, antibiotic prophylaxis should provide adequate drug levels in the tissue before, during, and for the shortest possible time after surgery to provide a reduced infection rate; be an effective agent against the bacteria that are most likely to cause the infection; and be bactericidal while at the same time being the least toxic agent available.

Spaey and colleagues reported a 4% prevalence rate of infection after orthognathic procedures in their cohort.[312] Among the infections that were sustained, 92% occurred at the SSRO site, 1% occurred at the Le Fort I osteotomy site, and only 0.5% involved the chin osteotomy location (Figs. 16-4 through 16-7). In their pilot study group, after completion of an SSRO, the authors placed a drain through the mandibular vestibule mucosa incision; this was removed the following morning. The prophylactic antibiotic regimen that was initially used did not have a drug level in place while the drain remained in or after its removal. Because of the high infection rate observed in the pilot study, the researchers changed the protocol to no longer involve the placement of a drain; to achieve a more meticulous mucosal wound closure; and to extend the time of prophylactic antibiotic use to 5 days after surgery. As a result, the infection rate at the SSRO site was dramatically decreased. The authors concluded that, in addition to an extended use of prophylactic antibiotics, the achievement of a sealed vestibular wound at the SSRO is essential to limit the infection rate.

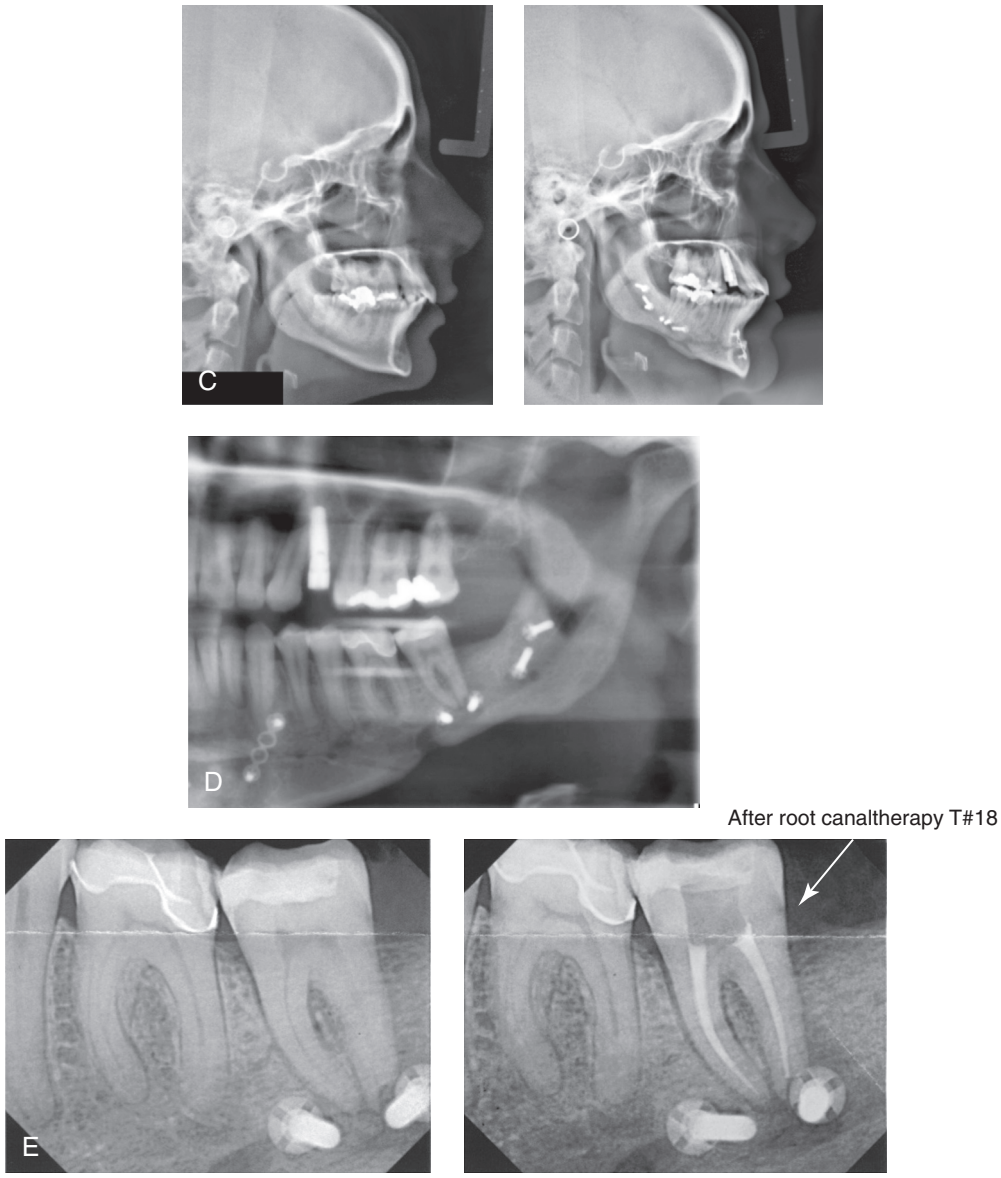
• **Figure 16-4** A woman in her early 30s with a primary mandibular deficiency growth pattern underwent a comprehensive orthodontic and surgical correction. This required the removal of dental compensation, including opening upper bicuspid extraction spaces for dental implants. Surgery included bilateral sagittal split ramus osteotomies, an osseous genioplasty, and anterior neck soft-tissue procedures. In-hospital and early at-home convalescence proceeded without incident. Five weeks after surgery, the patient returned to a more normal diet, to regular physical activities, and to her orthodontist's care. Two months after surgery, pain in the left mandibular second molar region with chewing was persistent. The tooth was also tender to percussion. A periapical radiograph revealed the proximity of a bicortical fixation screw to the distal root, with possible apical root resorption. The removal of the involved screw was offered. However, the patient chose root canal therapy followed by the relief of pain and the resolution of percussion tenderness. **A,** Profile and lateral cephalometric views before treatment. **B,** Oblique facial views before and after treatment.



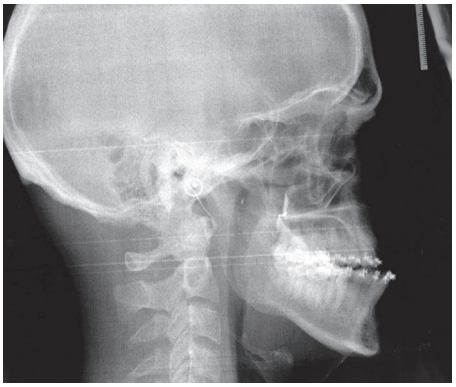
• **Figure 16-4, cont'd C,** Pretreatment and posttreatment lateral cephalometric radiographs. **D,** Left side Panorex image 2 months after surgery, with left mandibular second molar pain with chewing. **E,** A periapical radiograph is shown before and after successful root canal therapy (see Fig. 19-8).

In a randomized, double-blind study, **Ruggles and colleagues** tested two different antibiotic regimens in patients undergoing orthognathic surgery.[284] Both groups received preoperative and intraoperative antibiotics, whereas only one group continued 48 hours of postoperative coverage. The group that received no postoperative antibiotics had a 15% infection rate, whereas no infections were found in the group with extended antibiotic coverage.

Danda and colleagues completed a prospective study to evaluate the use of prophylactic antibiotics among patients who were undergoing orthognathic surgery.[78] The study patients (N = 150) were divided into two groups. Group I (N = 75) received a single dose of antibiotic prophylaxis. Group II (N = 75) received a full day of antibiotic prophylaxis. In Group I, 9.3% of patients (N = 7) developed infection, whereas only 2.6% (N = 2) of Group II patients did. The results indicate a clinically significant increased rate of infection with single-dose antibiotic prophylaxis as compared with a full day of antibiotic prophylaxis.

Kublefelt and colleagues reported on smoking as a significant risk factor for infection after orthognathic surgery.[176A] This was a retrospective cohort study of individuals (n = 286) who were undergoing one-jaw orthognathic surgery (i.e., bilateral SSRO [BSSRO] or Le Fort I osteotomy) during a 7-year period. All patients received a 1-week course of antibiotics. Patients ranged in age from 17 to 56.5 years (mean, 34.8 years). The overall infection rate was 9.1%. The only statistically significant identified risk factor for infection in these study groups was smoking history. The incidence of infection was 14.4% among

Orthodontic decompensation in progress



• **Figure 16-5** A 23-year-old man with a developmental jaw deformity and malocclusion was referred for surgical evaluation. He had also recently sustained trauma to the maxillary anterior region that involved a loss of the central incisors. The jaw deformity was characterized by maxillary deficiency in combination with relative mandibular excess. The patient agreed to a comprehensive surgical and dental rehabilitative approach. He also had lifelong difficulty breathing through his nose. After periodontal and restorative evaluations, the patient underwent orthodontic (dental) decompensation. Surgery included maxillary Le Fort I osteotomy in segments (arch expansion, horizontal advancement, and cant correction); bilateral sagittal split ramus osteotomies (asymmetry correction); osseous genioplasty (horizontal advancement); and septoplasty and inferior turbinate reduction. In-hospital and initial at-home convalescence proceeded without difficulty. Three weeks after surgery, increased swelling and tenderness along the right ramus region were appreciated, and intraoral drainage through the lateral ramus incision was recognized. The patient underwent exploration with Penrose drain placement as an office procedure under local anesthesia, and he was restarted on antibiotics. The drain was removed 1 week later, and the 10-day course of oral antibiotics was completed. Healing at all osteotomy sites remained on track. Five weeks after surgery, the patient returned to a more regular diet and physical activity without delay. The orthodontic appliances were removed 6 months after surgery. **A,** Presurgical facial and occlusal views with orthodontics in progress. **B,** Profile and lateral cephalometric views before surgery.

smokers and 7.0% among non-smokers. The site of infection was primarily the ramus region followed by the Le Fort I osteotomy region.

Interestingly, six cases of actinomycosis after orthognathic procedures have been reported.[216,293] **Ozaki and colleagues** reported a case of actinomycosis that occurred in the left submandibular area after SSRO.[249] The infection resolved after 2 months of antibiotic therapy.

NOTE: Current literature confirms that, for orthognathic surgery that includes SSRO, the following are true: 1) prophylactic antibiotics (preoperative, intraoperative, and postoperative) reduce infection rates 2) effective wound closure (without occurrence of dehiscence) will diminish infection rates 3) intraoral drains placed at the osteotomy site are counterproductive and 4) the incidence of infection is higher among smokers.

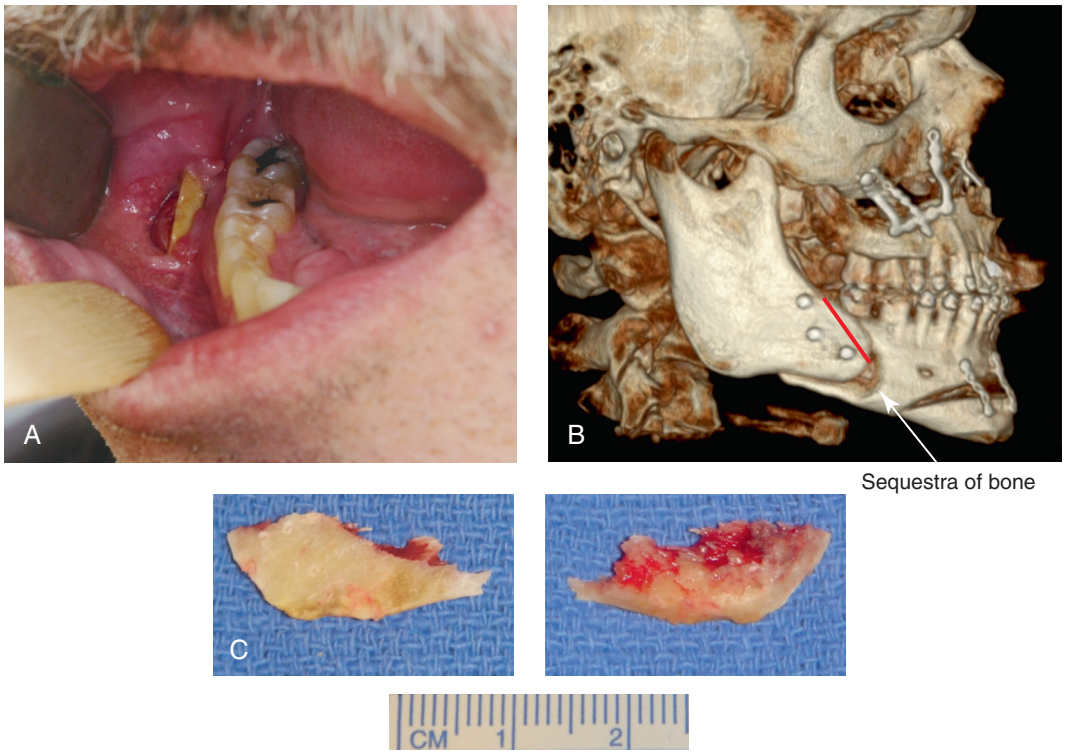
Instrument Breakage: Foreign-Body Reaction

Manikandban and colleagues reviewed the incidence and consequence of bur breakage within the surgical wound during orthognathic surgery.[210] The authors found that surgical bur breakage was not uncommon (5 out of 76 patients; 6.6%). They concluded that bur retrieval was not always advisable, because collateral damage to the hard and soft tissues may occur in the process. They recommended radiographic confirmation immediately after surgery and then clinical follow up for at least 1 year to confirm that no foreign body reaction or infection has occurred (Fig. 16-8).

Risks and Complications Specific to Sagittal Split Ramus Osteotomies of the Mandible

Unfavorable Sagittal Split Ramus Osteotomy

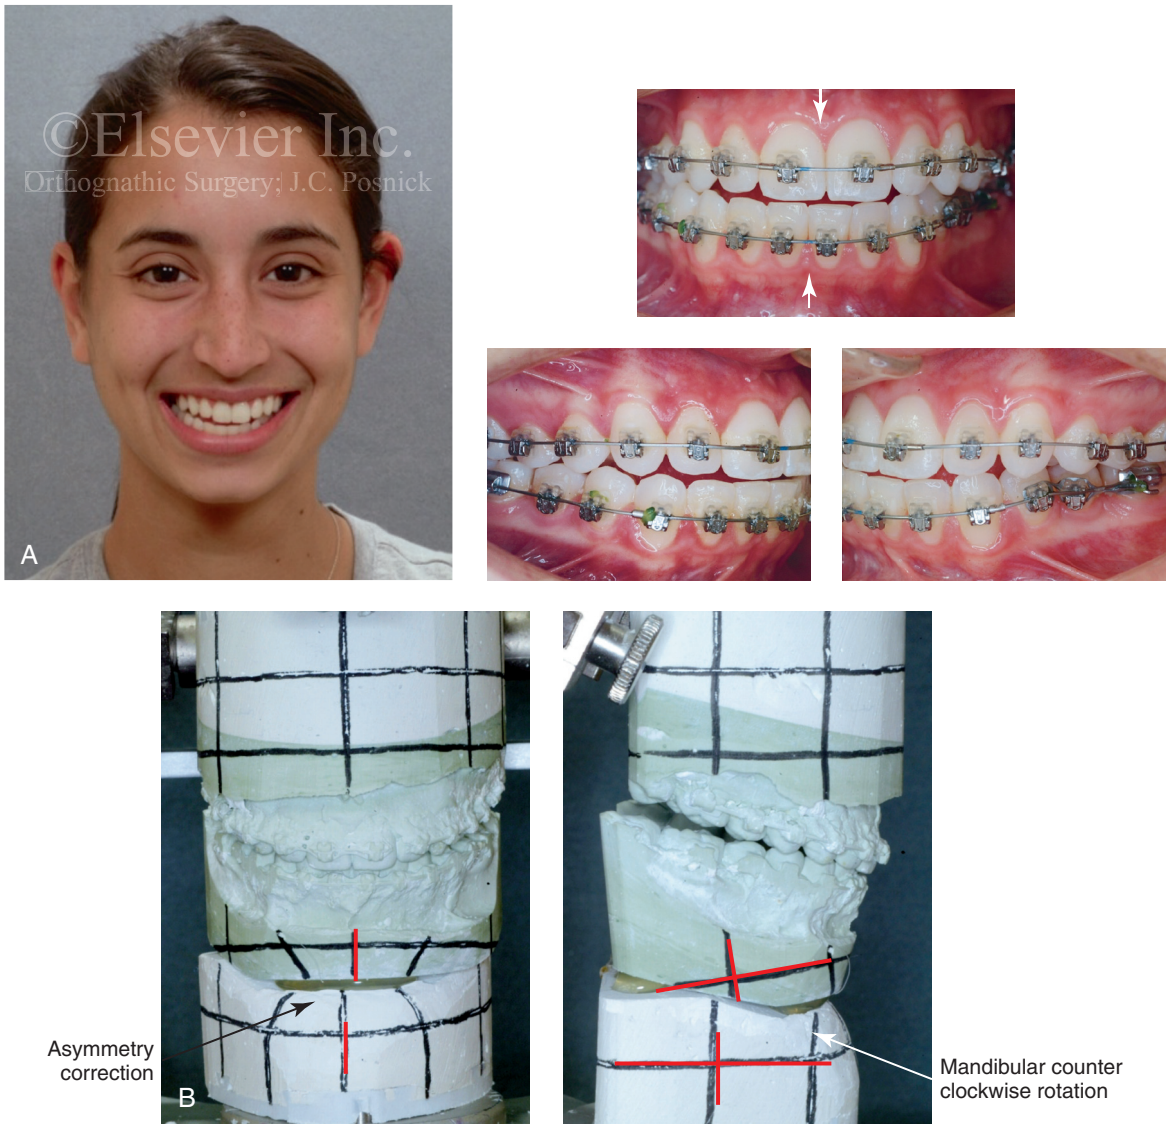
When completing an SRO, an unfavorable fracture (i.e., a "bad split") can occur.[23,42,139,162,206,243,334] The definition of a bad split varies from clinician to clinician. This author reserves the term *bad split* only for those SROs in which the condyle either remains with the distal segment, thus requiring a separate osteotomy (i.e., third piece), or shatters into a separate component (i.e., third piece) on its own (Fig. 16-9). Other less than ideal splits may include the following: 1) a separate fracture or piece of the buccal plate 2) a



• **Figure 16-6** A 50-year-old man with a short face growth pattern and obstructive sleep apnea underwent orthognathic surgery, including maxillary Le Fort I osteotomy; bilateral sagittal split osteotomies of the mandible; and an osseous genioplasty. Interpositional allogenic grafting was required in the maxilla and chin regions. At the 2-week postoperative visit, partial dehiscence of the right mandibular vestibular wound was recognized. The distal superior aspect of the proximal segment was visualized through the wound. There was minimal associated facial swelling and no abscess or fluid collection. In the office setting, a rongeur was used to remove the exposed bone, and the patient was restarted on antibiotics. The wound spontaneously closed over the next 10 days. Healing at the osteotomy site remained on track, and there was no long-term sequelae. (Note: If the inferior borders had been more closely aligned before the bicortical screw fixation, then dehiscence with the loss of the bone fragment may not have occurred.) **A,** Intraoral view of the right mandibular vestibular wound at 10 days after surgery with dehiscence and exposure of the superior aspect of the proximal segment. **B,** Computed tomography scan demonstrating the portion of the buccal shelf and the proximal segment that was resected with the rongeur. **C,** Specimen removed with a rongeur.

separate fracture or piece of the lingual plate posterior to the second molar; or 3) a separate fracture or piece of the coronoid process. All three of these splits are generally manageable without alteration of the expected postoperative recovery. When the buccal plate separates from the proximal segment, the fragment is either removed or additional plate and screw fixation is used to secure it. When the lingual plate separates from the distal segment, no additional fixation is generally required. The lingual bone fragment is either removed or left in place. When the coronoid process separates from the proximal segment, it is usually removed to limit the chance of ankylosis during the healing process.

Text continued on p. 498



• **Figure 16-7** A 20-year-old college student with an asymmetric mandibular excess growth pattern (Hemi-mandibular elongation) arrived for surgical evaluation. She had previously undergone orthodontic attempts to neutralize the occlusion without success. She agreed to a combined orthodontic and surgical approach. With the removal of orthodontic (dental) compensation, surgery was carried out. The procedures included bilateral sagittal split ramus osteotomies (asymmetry correction) and osseous genioplasty (horizontal advancement). By 5 weeks after surgery, postoperative swelling had generally subsided. A painless "lymph node" was palpable in the right submandibular region. It was not fixed to the skin or bone. Three months after surgery, what appeared to be a localized lymph node became tender with erythema and then with drainage through the skin. Cultures were carried out and showed no specific growth. An infectious disease consult was obtained, and Gram staining showed gram-positive rods. The patient was placed on amoxicillin and then Augmentin. The localized infection involved intermittent drainage but without a connection down to the bone. Four months after surgery, the patient agreed to undergo excision of the soft-tissue mass with primary closure and the reinstituting of antibiotics. Histopathology was unremarkable, and the cultures remained negative. The wound healed without complications. **A,** Facial and occlusal views with orthodontics in progress. **B,** Articulated dental casts that indicate analytic model planning.

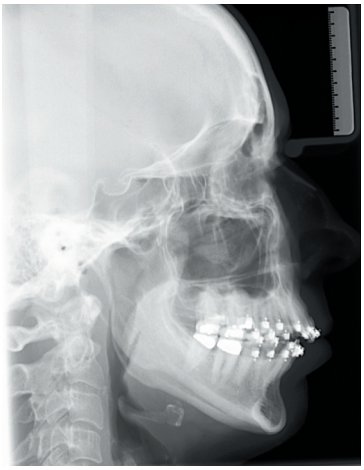
• **Figure 16-8** Individuals who are undergoing orthognathic surgery may experience intraoperative bur breakage. It is also not uncommon for orthodontic brackets, hooks, or ligatures to loosen with the potential for loss in the surgical field. Because of the small size of the lost objects within deep wounds, retrieval is not always advisable or possible. These foreign bodies can be visualized radiographically. Clinical follow up for at least 1 year is recommended to confirm that no foreign body reaction or infection has occurred. A Panorex radiograph is shown before and after orthognathic surgery. An orthodontic hook was lost in the right mandibular vestibular wound and can be seen on the Panorex radiograph. No negative sequelae resulted.



• **Figure 16-9** A woman in her mid 40s was referred for the surgical evaluation of asymmetric mandibular deficiency with secondary deformities of the maxilla. A longstanding flattening of the left condylar head with a loss of posterior facial height was felt to be responsible. There were no current symptoms of temporomandibular disorders, and the condyle was felt to be stable. The patient had an asymmetric Class II excess overjet anterior open-bite malocclusion. An orthodontic and surgical approach was selected. With orthodontic (dental) decompensation complete, surgery included maxillary Le Fort I osteotomy in segments (arch expansion and cant improvement); bilateral sagittal split ramus osteotomies (minimal horizontal advancement and asymmetry improvement); osseous genioplasty (horizontal advancement); redo septoplasty; and neck liposuction. During surgery, a "bad split" was appreciated on the left side. Nevertheless, the ramus osteotomy was secured with three bicortical screws. Radiographs the day after surgery confirmed a separate condylar component in the left ramus region. Posteroanterior and lateral cephalometric and Panorex radiographs were again taken 10 days after surgery, and these were suggestive of adequate segment approximation. At 5 weeks after surgery, left lateral mandibular facial swelling with mild tenderness persisted. At 8 weeks after surgery, a left posterior mandibular vestibular fistula was appreciated. In the operating room, the wound was opened to remove a buccal shelf and coronoid fragment as well as the fixation screws. Cultures confirmed *Escherichia coli, Enterobacter,* alpha-hemolytic *Streptococcus,* and *Candida.* Oral antibiotics were initiated, including clindamycin, ciprofloxacin, and Diflucan. At 11 weeks after surgery, there was a functional occlusion with good vertical mouth opening and a mild shift to the left. At 9 months after surgery, facial morphology and occlusion remained acceptable, and the orthodontic appliances were removed. **A,** Facial and occlusal views with orthodontics in progress. **B,** Profile and lateral cephalometric views before surgery.

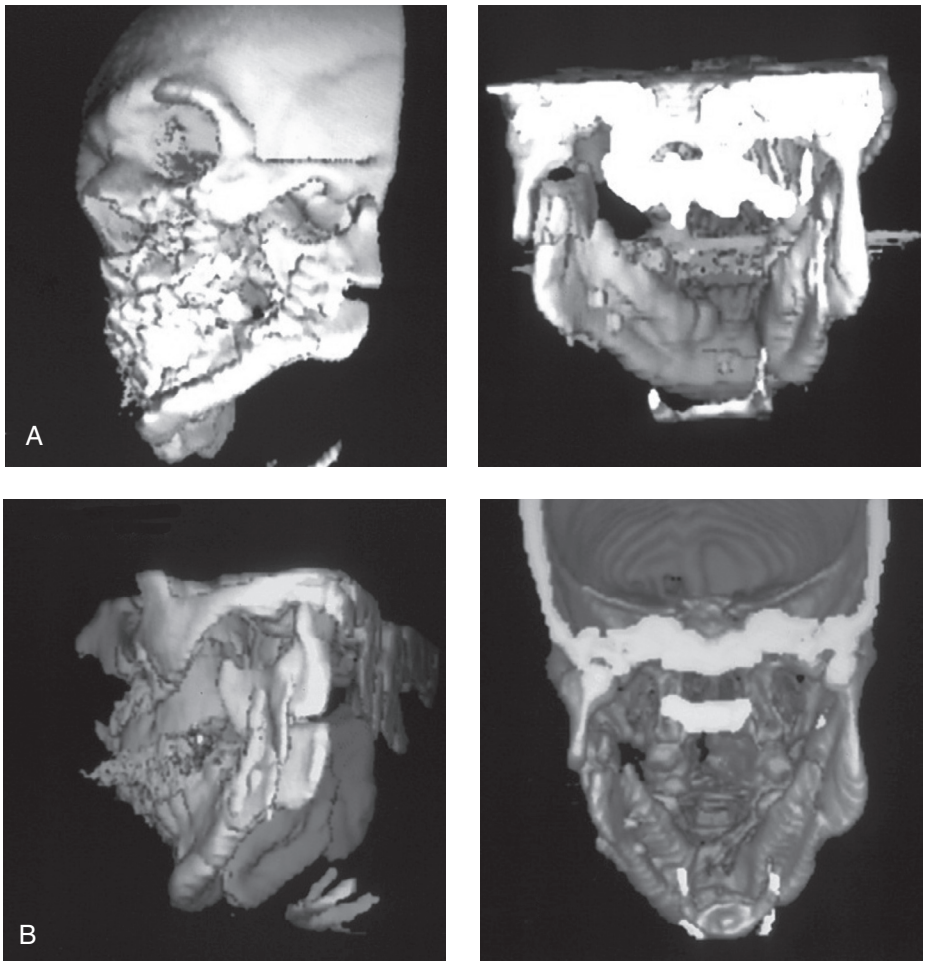
When the condyle separates as a third piece, intraoperative decisions will affect the postoperative recovery and occlusion (see Fig. 16-9). From the perspective of the occlusion, if the condyle or the medial pole remains with the distal segment, it will be as if no osteotomy on the ipsilateral side of the mandible was carried out. If no further action is taken, an intraoperative malocclusion should be recognized. To fully complete the ramus osteotomy, the surgeon must then separate (i.e., osteotomize) the condyle from the distal segment (i.e., create a third piece). The osteotomy should be carried out, with as much ramus left on the condylar segment (i.e., the third piece) as possible. Even when this type of bad split occurs, unless significant mandibular advancement is required for the correction of the jaw deformity, the successful healing of the segments will generally occur (see Figs. 16-9 and 16-10).

If the condyle separates (i.e., if a third piece is created) "high up," the result is similar to that of a high condylar neck fracture. There will not be a stable posterior stop unless the surgeon is able to carry out plate and screw fixation of the condylar component (i.e., the third piece) to the rest of the proximal segment. This may not be practical, and it will depend on the morphology of the condylar piece. The incidence of postoperative malocclusion will also be



• **Figure 16-10** A teenager with a cleft jaw deformity underwent orthognathic surgery that included a maxillary Le Fort I osteotomy in segments; bilateral sagittal split osteotomies of the mandible; and an osseous genioplasty. The sagittal split on the left side separated unfavorably. The proximal segment includes a condyle coronoid upper ramus component; an angle ramus component; and a buccal shelf component. The three components of the proximal segment were secured together and fixed to the distal segment with a combination of titanium plates and screws. Fortunately, the reduction was adequate, so healing occurred with favorable facial aesthetics, occlusion, and temporomandibular joint function. **A** and **B,** Three-dimensional computed tomography scan views of a "bad split" fixed into acceptable alignment during orthognathic surgery.

dependent on the directional change planned for the distal mandible. If the mandible is to be advanced a significant amount, there is a greater probability that the minimally stabilized condylar segment (i.e., the third piece) will not heal in an ideal location relative to the residual proximal and distal segments. Alternatively, if the mandible is to remain relatively neutral or is set back, there is a higher probability that the condylar segment will heal to the residual proximal and distal segments in a favorable way (see Fig. 16-9). As long as healing is associated with adequate mobility (i.e., mouth opening), then any residual malocclusion can typically be managed 6 to 12 months later with redo SROs, if desired (see Chapter 35).

Unfortunately, there is no consensus with regard to what combination of factors predisposes an individual to a bad split. The literature shows the incidence of bad splits to vary from 1% to 23%. A buccal plate fracture of the proximal segment, a lingual plate fracture of the distal segment, and a coronoid process fracture of the proximal segment are the most commonly reported "bad splits". Authors who consider these types of less than ideal osteotomies to be bad splits provide an explanation for the high incidence reported in some series. As previously stated, the majority of less than ideal separations (fractures) at the time of SSRO result in fixation challenges, most are not responsible for long-term negative sequelae.

The occurrence of a bad split is greatly reduced by keeping the medial osteotomy "short (not to far back) and low" (close to the occlusal surface of the mandibular molars) (Fig. 16-11). Using this technique a bad split as described should be a rare event (see Chapter 15).

Veras and colleagues evaluated risk factors and the functional and radiographic long-term results of a bad split.[350] They also completed detailed temporomandibular joint

examinations on patients with bad splits. Interestingly, they did not find the simultaneous extraction of a mandibular third molar in conjunction with an SSRO to be a risk factor for the development of a bad split. This is consistent with the research reported by Kriwalsky and colleagues,[174] Precious and colleagues,[268] and others (see discussion earlier in this chapter).

Inferior Alveolar Nerve and Mental Nerve Injury

Facial sensibility of the area affected by either an SSRO or a chin osteotomy occurs through the *mandibular nerve,* which enters the mandibular foramen at the medial surface of the ramus.* This area is adjacent to and in front of the inferior alveolar artery and vein and just inferior to the occlusal plane of the mandibular molar teeth. The mandibular nerve becomes the *IAN,* and it runs with its vessels within the canal and supplies sensation to the three molars and the two premolar teeth. It then divides into two terminal branches. The *incisive branch* supplies sensation to the canine and incisor teeth, whereas the *mental nerve* exits from the foramen to supply sensibility to the chin, the lower lip mucosa and skin, and the adjacent gingiva. Damage to the IAN during either the ramus osteotomies or when completing an oblique osteotomy of the chin may occur. During SSRO of the mandible, the IAN can be damaged by a bur on a rotary drill, a saw blade on a reciprocating saw, an osteotome, or during the placement of plate and screw fixation (Fig. 16-12).

Posnick and colleagues completed a study to clarify normal chin, lower lip, and gingival sensibility in adolescents and then compared the normal values with sensibility measurements in three distinct groups of adolescents 1 year after these individuals had undergone mandibular osteotomy.[261,263] One hundred fifteen subjects (230 mental nerves) were included in the study and divided into four groups. The first group included 67 individuals (Group I: n = 134 nerves; mean age, 18 years) who were undergoing orthodontic treatment; none had undergone orthognathic surgery. This group served as controls to determine the normal sensibility values of the chin, the lower lip, and the gingiva in adolescents. The remaining three groups were made up of adolescents who had previously undergone

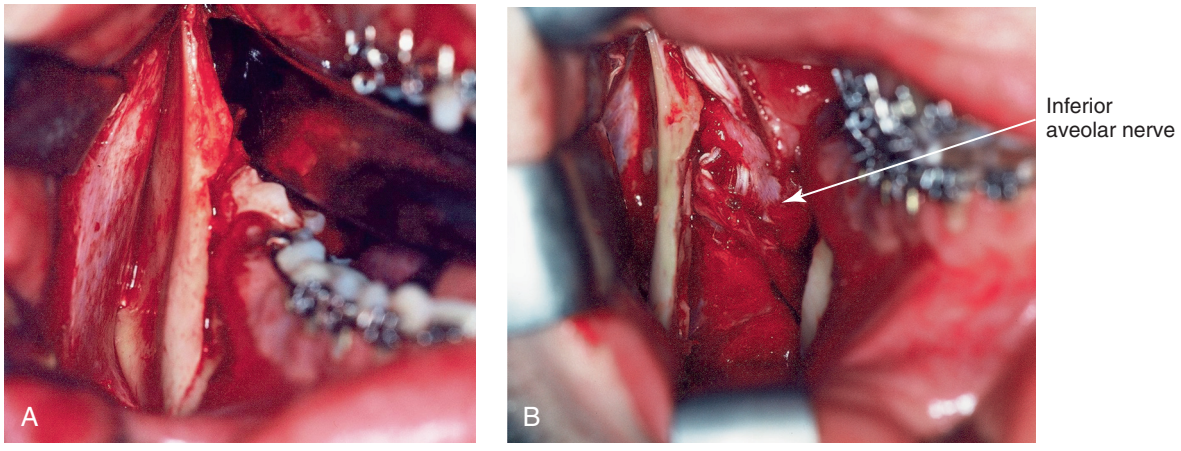
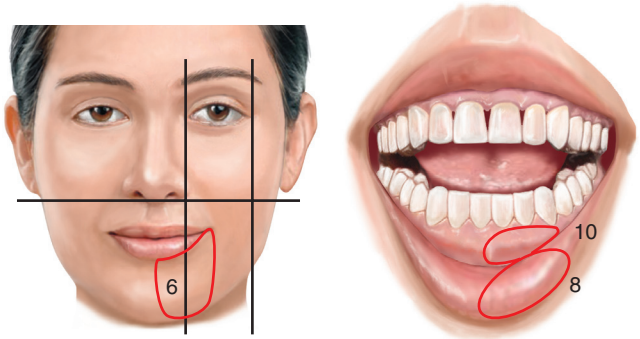
*References 3, 5, 6, 10, 12, 17, 18, 21, 37, 45, 51, 52, 55, 57, 65, 66, 69, 71, 88, 97-102, 106, 109, 112, 114, 121, 141-144, 160, 161, 166, 169, 193, 195, 196, 197, 227, 229-231, 234, 239, 258, 263, 265, 275, 277, 295, 296, 299, 301, 305, 327, 329-334, 344, 351, 354, 358-361, 369, 370, 368, 374, 376, 378, 380.



• **Figure 16-12** Intraoperative views of a right sagittal split ramus osteotomy. The demonstration of cortical cuts completed **A,** before and **B,** after the splitting (separation) and mobilization of the segments. The inferior alveolar nerve is visualized in the surgical field.

BSSRO of the mandible (Group II: n = 14 nerves; mean age, 19 years), osteoplastic genioplasty (Group III: n = 40 nerves; mean age, 19 years), or a combination of BSSRO and osteoplastic genioplasty (Group IV: n = 42 nerves; mean age, 19 years). Testing of Groups II, III, and IV was performed 1 year after the patients had undergone the indicated mandibular procedures. At the time of the 1-year postoperative examination, each patient was also asked to detail subjective impressions of current altered sensibility in the mandibular vestibular mucosa, the gingiva, the lower lip, and the chin region. The subjective questioning and objective testing were carried out by an occupational therapist who was trained in facial sensibility testing and familiar with the surgical procedures carried out. Fixed and reproducible coordinates in the area corresponding to the mental nerve were used for objective testing (Fig. 16-13). Three sensory modalities were tested at each coordinate for each involved nerve. Static two-point discrimination was measured with a MacKinnon–Dellon Disk-Criminator (Richardson Productions, Inc, Frankfort, Ill); vibratory thresholds were determined with a biothesiometer; and cutaneous pressure thresholds were measured with a set of Semmes–Weinstein monofilaments. Sensibility values at 1 year after operation for Groups II, III, and IV were compared with the mean normal control values established for Group I. A subjective awareness of alterations in the sensibility of the chin, lip, or gingiva region 1 year after BSSRO was reported in 2 patients in Group II (29%), in 2 patients in Group III (10%), and in 14 patients in Group IV (67%). Interestingly, only 2 of these 18 patients considered the residual sensory loss problematic. The mean objective sensibility values of the three sensory modalities tested were highest among patients from Group IV. Significant differences were found only between the mean two-point discrimination of Group IV patients as compared with the control group in the chin skin area. Thus, 1 year after BSSRO, only 29% of patients had residual subjective awareness of sensory alteration along the distribution of the mental nerve. After an osseous genioplasty, there was only a 10% incidence of long-term subjective diminished sensibility. One year after a combination of BSSRO and osteoplastic genioplasty, 67% of patients experienced varying degrees of residual subjective loss of sensation in the chin and lip region.



• **Figure 16-13** Illustration of sites for sensibility testing in the inferior alveolar and mental nerve distribution. In a study carried out by Posnick and colleagues, coordinates 6, 8, and 10 located within each of the circled areas were tested bilaterally.

Espelan and colleagues completed a 3-year postoperative survey of patients who had undergone SSRO (N = 583 subjects) and found that that 36.8% of the study patients reported impaired sensation over the long term.[96A] Westermark and colleagues completed a retrospective study of patients who had undergone SSRO and concluded that nearly 100% of the patients experienced impaired sensation and sensory function.[358] This is also consistent with the findings of **Essick and colleagues**[97] and **Teerijoki-Oksa and colleagues.**[332,333] The exact reasons why, over time, most patients experience only a degree of simple loss of sensation—whereas some continue to experience active sensations that are not normally present and an even smaller percentage of those with active sensations subjectively describe them as uncomfortable or painful (dysesthesia)—are not known. **Zuniga and colleagues** reported a 5% incidence of dysesthesia of the IAN after SSRO.[380,381]

Turvey reported a 5.5% incidence of IAN lacerations at the time of SSRO.[343] **Van Merkesteyn and colleagues** documented a visible injury in the IAN at the time of SSRO in 7 out of 124 patients (6%).[347] The term *traumatic neuroma* is used to describe the formation of a bulbous mass that develops at the end of a proximal nerve stump after partial or complete nerve transection. The lesion represents an exaggerated relative hyperplasia (i.e., healing) response to a nerve injury. Neuroma symptoms range from paresthesia to severe paroxysmal or persistent pain. Despite the incidence of partial or complete transection of the IAN at the time of SSRO, few cases of traumatic neuroma have been documented. This is likely because the healing transected nerve remains deep in the medullary cavity of the mandible. It is known that a healing nerve stump within bone is rarely painful. The few reported cases of neuroma after SSRO have confirmed the location to be within the soft tissues along the inferior border of the mandible.[120,121]

Essick and colleagues completed a clinical trial that determined that the magnitude and duration of the patient-reported *burden of altered sensation after SSRO* was lessened when facial sensory retraining exercises were performed in conjunction with standard mouth-opening exercises as compared with the group of patients who performed only mouth-opening exercises.[97] The authors defined the term *burden* as the person's reporting of subjective impressions of numbness or unusual sensations (i.e., dysesthesia) in the face, the perioral region, and or oral region. One interpretation of the study findings is that patients who perform facial sensory retraining become more introspective with regard to their altered sensation, which leads to a greater acceptance of their sensory loss by 6 months after surgery. Consistent with this interpretation was the finding that sensory retrained patients initially viewed numbness and decreased sensitivity as more problematic early during recovery but as less problematic later during recovery than did the group of patients who did not undergo retraining.[258]

The retraining sessions were held at 1 week, 1 month, and 3 months after surgery. The levels of instruction for the sensory retraining were designed to increasingly challenge patients' sensory discrimination abilities in a manner similar to that of the early and late phases of sensory retraining commonly used after injuries to the sensory nerves of the hand.[120,121] Through sensory retraining, individuals learn to discriminate moving touch from non-moving touch; the orientation of moving touch; and the direction of moving touch (see Chapter 11). **Poort and colleagues** completed a literature review of methods that are used to test for sensory loss and recovery after IAN injury and recommended that clinicians and researchers use the following two measurement tools: 1) a light touch test with Semmes–Wienstein monofilaments for grading sensation; and 2) a visual analog scale–based questionnaire to evaluate the individual's subjective sensibility.[261A] If clinicians were to adopt consistent measuring techniques, improved communication with regard to sensory loss and level of recovery after interventions would likely follow.

A dilemma that surgeons continue to face is what to do in the operating room when the laceration of the IAN is witnessed. The question raised asks if there is any significant long-term advantage for the patient to undergo either primary or delayed micro repair of the lacerated IAN. Although the concept of the immediate repair of a witnessed IAN transection is appealing, the practicality of this maneuver and the patient's long-term improved results (i.e., greater sensory return and decreased dysesthesia) have not been statistically confirmed. The increased operative time and the potential risks of losing focus on the primary orthognathic objectives must also be considered. **Tay and colleagues** reported four cases of immediate micro-neural repair of an IAN that was transected during SSRO.[334] This represented 4 out of 260 (2%) SSROs completed at their center. One of the four patients who sustained IAN laceration was apparently lost to follow up. Interestingly, the location of IAN transection in the remaining three study patients was at the anterior and inferior aspect of the osteotomy along the buccal shelf between the first and second molars; this is a recognized "danger zone" for IAN transection during SSRO. When there is a moderate to severe degree of mandibular hypoplasia with the need for buccal shelf extension of the proximal segment to achieve successful approximation of the bone after advancement, this risk may increase. In the study by Tay and colleagues, the three study patients underwent immediate repair of the IAN (i.e., neurorrhaphy) by a trained microsurgeon and then received follow for 1 year.[334] The microsurgeon's technique included the complete surgical release of the nerve from the mandibular foramen to the mental foramen followed by approximation and repair with the use of 6-0 microfilament suture under microscope magnification. The increased time of the surgery was approximately 3 to 4 hours. Although the authors felt favorable regarding the outcomes of their patients, the level of sensory return that was documented was not proven to be significantly better than expected after the simple approximation of the nerve endings within the ramus of the mandible.

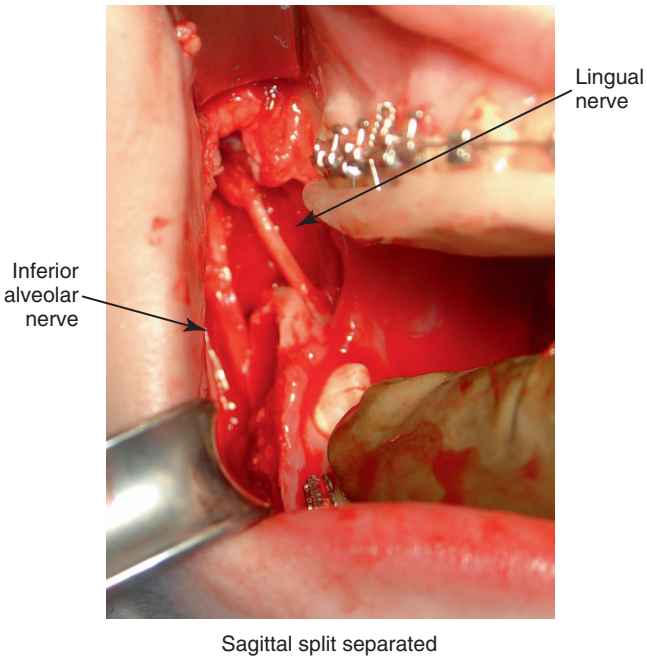
NOTE: This author believes that a controlled study documenting significantly better sensory recovery after direct micro-neural repair that occurs via the simple approximation of the cut edges of the IAN in the setting of an SRO would be required to justify the added time and risk of the repair.

Lingual Nerve Injury

The incidence of injury to the lingual nerve during SSRO is not precisely known, but it is assumed to be rare.[35,132,145,147,279,289-291,327] **Becelli and colleagues** completed a retrospective analysis of complications after SSRO and found a 0.6% rate of lingual nerve dysfunction among 482 osteotomy patients during the first postoperative week. The authors documented complete resolution of this injury after 12 months of follow up in the study group. Interestingly, lingual nerve injury at the time of the removal of mandibular wisdom teeth as an isolated procedure is also estimated to be in the same range (i.e., <1%).[260] When a lingual nerve injury does occur with SSRO, it likely occurs during subperiosteal dissection along the medial ramus; when using a rotary drill (e.g., with a Lindeman bur); or when using the reciprocating saw (e.g., during a medial ramus cortical cut). It may also occur with use of the electrocautery to control bleeding, during screw fixation, or when closing the wound if the lingual nerve is caught within the suture tie (Fig. 16-14).

Pogrel and Hung Le completed a cadaver study that demonstrated that different modalities (e.g., sharp scalpel laceration, fissure bur injury, retraction stretch injury) produced different types of nerve injury, both clinically and histologically.[261] The clinical recovery of the injured nerve is believed to be primarily related to the type of injury sustained. For this reason, the treatment recommended should also vary in accordance with the type of injury sustained. Data reveal that 57% of lingual nerve injuries were unknown to the surgeon at the time; therefore, the type of injury could not be accurately ascertained.[86]

Unfortunately, many of the published lingual nerve injury studies are retrospective case series or questionnaire surveys.[260] The studies also frequently combine both lingual and IAN injuries. The literature recommends that observed injuries and those involving a foreign object causing compression or laceration (e.g., endodontic filling material, bone fragment, broken instrument) should be treated immediately. Caution is warranted when interpreting two-dimensional radiographic views when making decisions about impingement on the nerve by a foreign object (e.g., a fixation screw). Three-dimensional computed tomography scans may be useful to help make the determination.



• **Figure 16-14** A completed right sagittal split ramus osteotomy. The separation of the segments demonstrates both the inferior alveolar and lingual nerves. The lingual nerve is only occasionally visualized in the surgical field.

Patients with severe hypoesthesia who are demonstrating no sensory improvement at approximately 3 months after treatment may be surgical candidates. Those with at least some documented continuous sensory improvement are best managed conservatively.

Susarla and colleagues used a retrospective cohort study design to address whether the early repair of a lingual nerve injury improves functional sensory recovery.[324] The study sample was composed of 64 subjects with lingual nerve injuries who underwent repair with a mean time between injury and repair of 153 days (31 to 1606 days). Twenty-two percent of the subjects underwent early repair (i.e., <90 days after injury). The nerves were repaired either through direct suture (77%) or surgical exploration with decompressive neurolysis (23%). Ninety-three percent of the study subjects in the early repair group achieved functional sensory recovery within 1 year as compared with only 63% in the late repair group. Although early repair shows statistical benefits for the achievement of functional sensory recovery, it must also be assumed that a percentage of those individuals who submitted to early repair would have gone on to achieve adequate recovery through the natural course of events. A randomized clinical trial would be required to clarify any clear advantage of early repair.

A study by **Bagheri and colleagues** suggests that, for some individuals, secondary repair of a lingual nerve or IAN injury will result in the regaining of acceptable sensory function as classified by the Medical Research Council Scale.[17] However, at least some of those who are undergoing secondary repair will show little improvement, and the prospect of deterioration is not insignificant. The evaluation and management of both lingual and IAN dysfunction after an SSRO remains a challenging clinical dilemma. The specific etiology and incidence of persistent sensory deficit and neuropathic pain after SSRO remains poorly understood. Nevertheless, prudent care suggests that, when a lingual nerve injury occurs during a ramus osteotomy, the surgeon is obliged to offer evaluation by a knowledgeable peripheral nerve surgeon within 3 to 6 months. This will ensure that the injured individual receives the information needed to make a personal decision about how to proceed.

Facial Nerve Injury

Reports of injury to other than sensory nerves are primarily restricted to the facial nerve, and these mainly occur during mandibular procedures.[60,68,77,79,226,272,287] A retrospective study conducted by de Vries and colleagues after SSRO (N = 1747) found an incidence of seventh nerve palsy of 0.26% (9 patients).[83] Choi and colleagues found an incidence of facial nerve palsy of 0.1% among 3105 patients who underwent sagittal split ramus osteotomies.[60]

Significant Bleeding

In current practice, significant bleeding is rarely encountered at the time of SSRO.[16,64,177,184,185,191,207,253,288,303,306,326,372] In 1972, a 38% incidence of major intraoperative hemorrhage was reported; in 2005, an incidence of only 1% was reported.[184,257] The vessels to consider include the *maxillary artery* and its branches; the *retromandibular vein;* and the *facial artery and vein.* Behrman reported about two patients with excessive bleeding in which he carried out ligation of the external carotid artery, although doing so was relatively ineffective for controlling the hemorrhage.[23] In 1985, Turvey reported the incidence of troublesome hemorrhage to be 1.2%; the inferior alveolar and facial arteries were the sources.[322] Acebal-Bianco and colleagues reported about the laceration of the facial artery during SSRO in two patients with successful management.[2] Van Merkesteyn and colleagues discussed difficult-to-control bleeding from the inferior alveolar and facial arteries in two patients.[257] Teltzrow and colleagues reported bleeding from the retromandibular vein to be the most common source of severe hemorrhage after SSRO.[335]

The occurrence of a *false aneurysm* (i.e., pseudoaneurysm or traumatic aneurysm) after an elective mandibular ramus osteotomy is uncommon. Precious and colleagues reported three cases of false aneurysm after SSRO and reviewed the pertinent literature.[269] A false aneurysm will present as a delayed phenomenon, usually 1 to 16 weeks after injury. These conditions are thought to result from a partial transaction of an artery (i.e., a facial artery) that leads to the extravasation of blood under pressure into the surrounding soft tissues. The resultant hematoma organizes, and this is followed by fibrous pseudocapsule and

then endothelialization. A pulsatile and expanding mass characterizes a false aneurysm. The difficulty of this situation is related to the making of an accurate and timely diagnosis. The treatment approaches include primary surgical resection, arterial embolization, or arterialization followed by surgical resection. Superselective arterial embolization alone is the current preferred approach, whenever feasible.

The surgeon's best protections against these unusual vascular events when carrying out a sagittal split ramus osteotomy remain the following: 1) careful patient selection 2) meticulous technique 3) good intraoperative assistance 4) protective instrument placement and 5) fine control of power tools. When severe hemorrhage does occur after SSRO, interventional radiology procedures versus the direct ligation of the involved vessels must be considered.

Risks and Complications Specific to Le Fort I Osteotomy

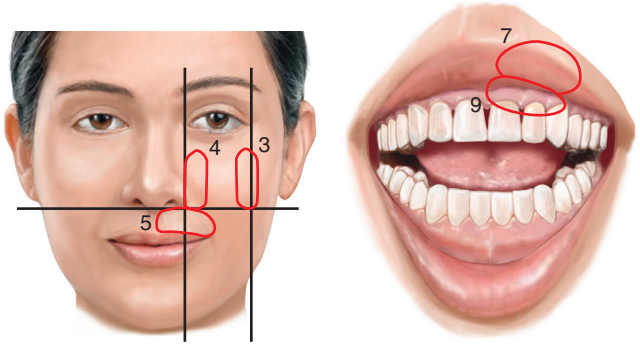
Infraorbital Nerve Injury

Sensory innervation of the area affected by the Le Fort I osteotomy is mainly through the maxillary division of the trigeminal nerve. During the Le Fort I osteotomy, the three superior alveolar nerves on each side are transected as part of the osteotomy, and the terminal labial branches of the infraorbital nerve are transected as part of the mucosal incision. After the infraorbital nerve emerges from the infraorbital foramen, it is also subject to trauma. A degree of injury to the infraorbital nerve at the time of Le Fort I osteotomy that results in temporary paresthesia is expected, whereas permanent dysesthesia of the cheek skin, the upper lip, the palate mucosa, and the gingiva is thought to be less common.* The nerve injury may result from compression or stretching, and direct injury may result from saw blades, burs, or surgical instruments (Fig. 16-15). The patient's age and gender will also be factor when considering nerve recovery and the occurrence of dysesthesia.

Posnick and colleagues objectively measured facial sensibility in adolescents (with and without cleft lip and palate) 1 year after Le Fort I osteotomy.[263] Fifty-nine individuals (118 infraorbital nerves) were included in the study and divided into three groups. The first group (N = 30) included subjects with unilateral cleft lip and palate (mean age, 18 years; with jaw deformity). The second group (N = 12) included subjects with bilateral cleft lip and palate (mean age, 19 years; with jaw deformity). All of these patients had undergone cleft lip and palate repair earlier during their lives; none had an associated craniofacial syndrome, developmental delay, or systemic neurologic impairment. The third group (N = 17) consisted of subjects without clefts or syndromes (mean age, 19 years) but with a developmental jaw deformity. Facial sensibility testing was conducted in the three groups 1 year after the Le Fort I osteotomy. Each patient was also asked about his or her subjective impressions of altered sensibility in the maxillary vestibular mucosa, the gingiva, the upper lip, or the cheek region at the 1-year examination. Previously defined fixed and reproducible coordinates were used for objective testing in the area that corresponds with the infraorbital nerve (Fig. 16-16).[267] Three sensory modalities were tested bilaterally at each coordinate. Static two-point discrimination was measured with a MacKinnon–Dellon Disk-Criminator. Vibratory thresholds were determined with the biothesiometer, and cutaneous pressure thresholds were measured with a set of Semmes–Weinstein monofilaments. The data was compared with the mean normal values that had been previously established for adolescents with and without cleft lip and palate before any orthognathic surgery.

The data confirmed that, at 1 year after Le Fort I osteotomy, none of the patients reported any subjective awareness of alterations in the sensibility of the maxillary vestibular mucosa, upper lip, or cheek regions. No significant differences were found in the mean postoperative values at each coordinate among the three groups in any of the sensory modalities tested. No significant differences were found

• **Figure 16-15** Intraoperative view after a circumvestibular incision for exposure to complete a Le Fort I osteotomy. The infraorbital nerve is visualized.



• **Figure 16-16** Illustration of the infraorbital nerve sensibility distribution. Coordinates 3, 4, 5, 7, and 9 are fixed sites that were used by Posnick and colleagues for sensibility testing.

*References 7, 52, 57, 71, 97-99, 120, 154, 160, 161, 261, 264, 265, 267, 273, 295, 323, 380, 381.

between the preoperative and postoperative pressure and vibratory threshold values in each patient group. The mean postoperative static two-point discrimination values were higher than the preoperative values in all areas tested and in all patient groups, but significant differences (i.e., $P < .05$) were found only in the anterior cheek skin area (coordinate 3) in the patients with unilateral cleft lip and palate on both the cleft and non-cleft sides. The study carried out by Posnick and colleagues confirmed the clinical impression that permanent functional sensory alteration of the soft tissue supplied by the infraorbital nerve is rare among teenagers and young adults after Le Fort I osteotomy.

Thygesen and colleagues recently looked at risk factors for paresthesia and dysesthesia of the infraorbital nerve after Le Fort I ostoeomy.[337] Their results are somewhat different from those of Posnick and colleagues. The authors found objective changes in somatosensory function 12 months after Le Fort I osteotomy in 7% to 60% of patients, depending on the site at which the sensory measurement was carried out (i.e., skin, gingiva, or palatal mucosa). The authors did not report instances of significant dysesthesia associated with the sensory loss in any patient. Despite a degree of subjective sensory loss at 12 months after surgery, all of the study patients were satisfied with the results of their operation, with 100% saying that they would do it again.

Visual Disturbances

Blindness

Decreased visual acuity (blindness) is a rare complication of Le Fort I osteotomy.* Although the exact mechanism of injury to the optic nerve has not been clarified, atypical fracture patterns that extend upward to the skull base from the pterygomaxillary (PM) separation at the time of downfracture have been implicated.[180,309,340,366] Girotto and colleagues reported on three cases of visual loss after elective standard Le Fort I osteotomy.[115] All three cases were presumed to be straightforward and were performed by experienced surgeons. The authors hypothesized that the unpredictable nature of the PM dysjunction may result in the extension of fracture to the skull base or generate deforming forces to the optic canal, with compression and pressure placed on the optic nerve. Lanigan reviewed the literature up through 1993 and reported two cases of blindness after Le Fort I osteotomy.[188] Bendor-Samuel and colleagues reported one additional case of blindness.[28] Lo and colleagues reported two cases of monocular blindness in 94 consecutive cleft palate patients who underwent mixed dentition maxillary (Le Fort I) osteotomy with osteodistraction with the use of the RED II Distraction System (KLS Martin, Mühlheim, Germany) during a 4-year period.[154] Although the exact etiology could not be clarified by Lo and colleagues, they stated that the PM disjunctions were performed at a higher level to avoid tooth bud injury in their patients with cleft palates during the mixed dentition. Therefore, the osteotomies were closer to the skull base and the orbit. The authors also speculated that the hard palate in the tuberosity region and the PM junction may have been more sclerotic as a result of the repaired cleft palate, thereby making precise PM disjunction less predictable.

Of the nine reported cases of blindness after Le Fort I osteotomy, five were of unknown cause, one was due to arterial aneurysm, two were attributed to propagation of the PM disjunction fracture through the skull base, and one was the result of the hypoperfusion of the optic nerve. There was no recovery in three cases, light perception returned in three, hand movements were visible in one, fingers could not be counted in one, and visual acuity showed much improvement in one. Interestingly, a majority of the reported cases of monocular blindness were in individuals born with cleft lip and palate. These patients had all undergone primary lip and palate repair, and several had previously undergone unsuccessful Le Fort I osteotomies. This likely represents a higher than average risk group for the rare complication of monocular blindness.[194]

Extraocular Cranial Nerve Dysfunction

Newlands and colleagues identified five cases of abducens palsy, three cases of oculomotor palsy, and one case in which both palsies were present together.[129,135,199,237,307,356] Most reported cases of extraocular nerve dysfunction after Le Fort I osteotomy occur immediately after surgery, although it has been reported up to 5 days postoperatively.

Nasolacrimal Apparatus Dysfunction

Tearing dysfunction has been reported after Le Fort I osteotomy by a number of authors; this involves either a lack of or excessive tearing.[202,210,211,300,338] A lack of tearing is thought to have occurred as a result of damage to the greater petrosal or Vidian nerve, which could interrupt parasympathetic supply to the lacrimal gland. Excessive tearing is thought to be related to nasolacrimal duct damage.

Significant Bleeding

Vascular complications (i.e., excessive bleeding)—either immediate or delayed—after Le Fort I osteotomy are rare.* The reported cause of the delayed bleeding is generally a partial laceration of a vessel with an *aneurysm* or an *arteriovenous fistula formation* (i.e., false aneurysm). The confirmation of a traumatic vascular abnormality is best made by angiography. This condition most frequently occurs in the internal maxillary artery or in the internal carotid artery region. The presentation of bleeding from the nose and occasionally from the oral cavity early after surgery is the typical clinical event. When massive epistaxis occurs soon

*References 28, 31, 43, 54, 58, 59, 67, 70, 115, 148, 188, 198, 199, 274, 278, 286, 339.

*References 4, 15, 40, 41, 64, 74, 116, 123, 126, 134, 136, 140, 168, 181, 183, 185, 187, 189, 190, 204, 205, 219, 236, 240, 241, 280, 302, 306, 308, 310, 316.

after Le Fort I osteotomy, the differential diagnosis may include coagulopathy, bleeding from a partially resected inferior turbinate, or bleeding from a large artery (i.e., the internal maxillary artery). Angiography with the possible need for embolization should be considered. A frequent palliative (but temporary) treatment approach is the packing of the nose. This is likely to immediately control bleeding; however, over time, a false aneurysm may form, and rebleeding (i.e., recurrent epistaxis) is typical.

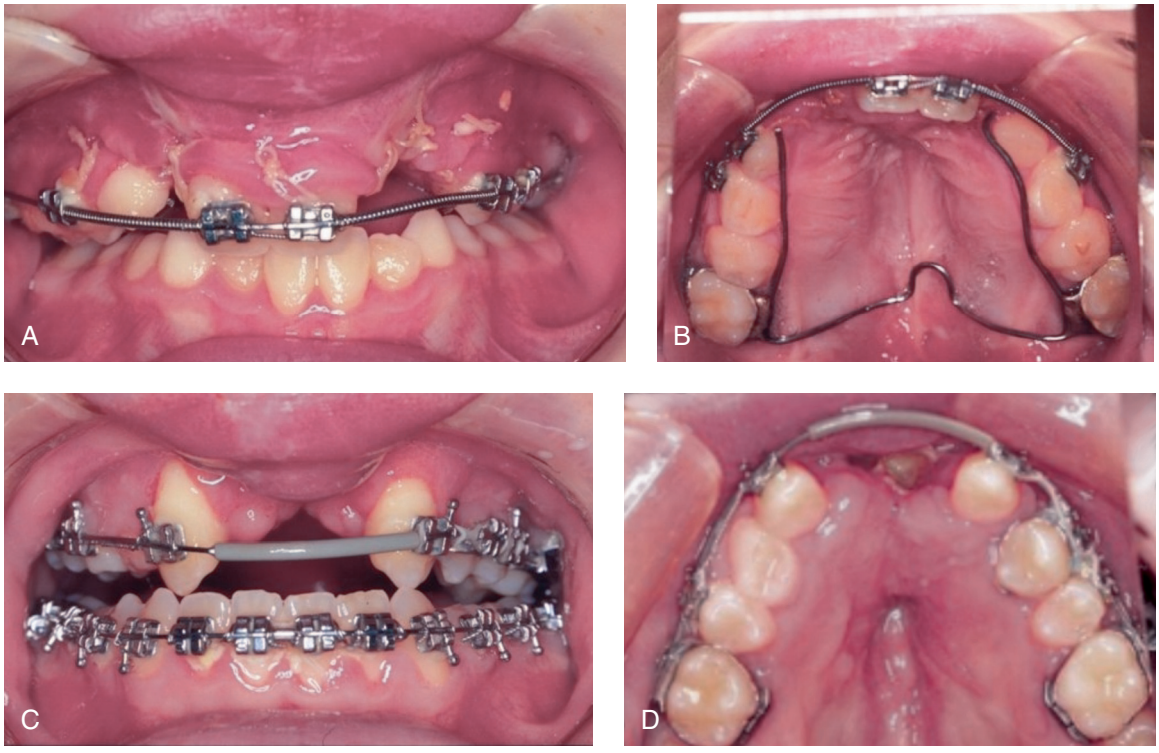
Procopio and colleagues described one patient (a 37-year-old woman who had undergone Le Fort I down-fracture) whose epistaxis occurred 2 hours after surgery and who was treated with anterior nasal packing.[270] Seven days later, she was taken back to surgery to reposition her maxilla for the treatment of malocclusion. No source of excessive bleeding was found. Further epistaxis occurred on days 21, 53, 63, 85, and 115. These episodes were treated with nasal packing, which resulted in resolution for short periods of time followed by rebleeding. On day 115, angiography and a computed tomography scan were completed. A false aneurysm of the sphenopalatine artery was identified and successfully embolized.

The standard *deliberate hypotensive anesthesia* techniques used during Le Fort I down-fracture can mask a partial laceration of the sphenopalatine or descending palatine artery. It is recommended that ligation or cauterization of the descending palatine artery be carried out when partial laceration occurs. It is also suggested that the orthognathic patient be allowed to emerge from hypotensive anesthesia before wound closure in an attempt to identify any major bleeding before the patient leaves the operating room.

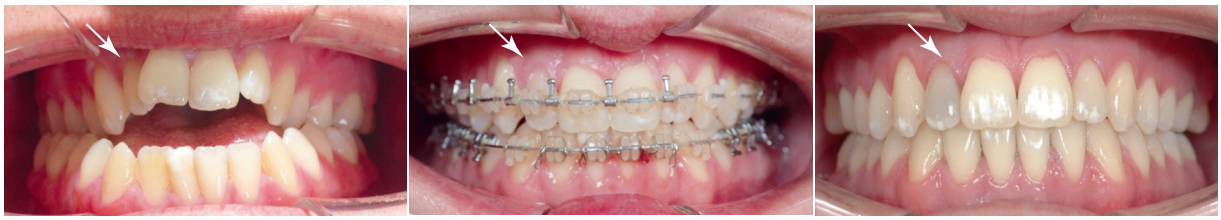
Aseptic Necrosis of Maxilla

A rare but serious complication of Le Fort I osteotomy is ischemic necrosis.[25,27,38,44,86,87,124,128,179,182,235,251,271,298,373] The severity of this postoperative complication is related to the degree of vascular compromise of the down-fractured maxillary segments. Reported sequelae of vascular compromise include infection, mucosa sloughing, periodontal defects, pulpal changes, malunion or nonunion, and the partial or complete loss of the maxilla and dentition (Figs. 16-17, 16-18, and 16-19).

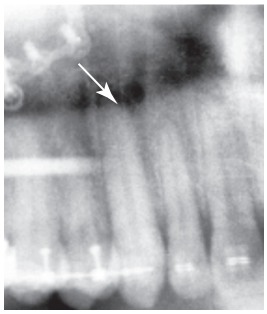
The biologic basis for maxillary (i.e., isolated segmental, down-fracture Le Fort I, and down-fracture Le Fort I with segmentation) osteotomies used in orthognathic surgery was extensively investigated in experimental animals by Bell and colleagues with the use of microangiographic and



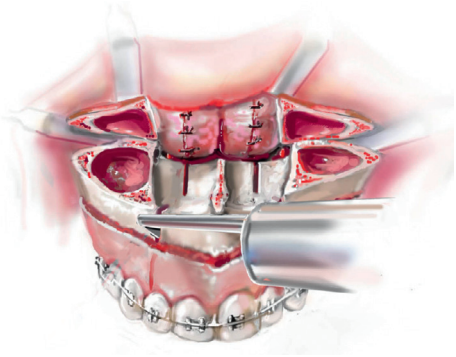
• **Figure 16-17** An individual who was born with a bilateral cleft lip and palate was treated at another institution. During the mixed dentition, he underwent unsuccessful iliac (hip) bone grafting and fistula closure. The premaxilla remained mobile, with residual alveolar clefts. When he was 17 years old, he underwent maxillary Le Fort I osteotomy, also at another institution. Unfortunately, given the residual alveolar clefts, the circumvestibular incision that was used resulted in circulation injury to the premaxilla (i.e., aseptic necrosis). Unless the bilateral cleft is successfully grafted through at least one of the alveolar sites, a circumvestibular incision that cuts through the labial vestibule of the premaxilla will predictably result in aseptic necrosis. **A** and **B,** Occlusal and palatal views are shown during the mixed dentition after unsuccessful grafting. **C** and **D,** The same views are shown during the teenage years after unsuccessful Le Fort I osteotomy with aseptic necrosis of the premaxilla and the resulting oronasal fistula.



Prior to treatment | 5 weeks after surgery | 6 months after surgery

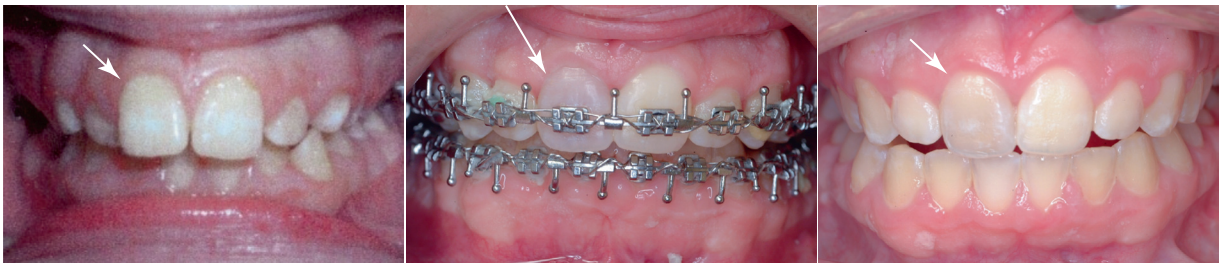


5 weeks after surgery



• **Figure 16-18** A man in his 20s presented with a maxillary deficiency and a relative mandibular excess growth pattern. He underwent orthodontics and reconstruction, including a Le Fort I osteotomy in three segments (i.e., interdental cuts between the lateral incisor and the canine on each side). Approximately 3 months after surgery, the right lateral incisor crown was noted to be dark in color. No other symptoms occurred. A postoperative radiograph shows the interdental osteotomy site. There was no direct injury to the dental root on either side of the osteotomy. The pulp of the tooth was treated with root canal therapy. Bleaching is planned to whiten the crown. Occlusal views are shown before orthodontics, at 5 weeks after surgery, and after successful reconstruction. An illustration and a maxillary model show the location of segmental osteotomies.

Pulpal necrosis



Pre treatment | 5 weeks after Le Fort I | 1 year after Le Fort I

• **Figure 16-19** Occlusal views are shown of a teenage girl with a long face growth pattern. She underwent an orthodontic and surgical approach. The surgery included maxillary Le Fort I osteotomy without segmentation. By 5 weeks after surgery, the right maxillary central incisor was noted to be dark in color. No other symptoms occurred. A postoperative radiograph showed no signs of root injury or periapical pathology. The pulp of the tooth was treated with root canal therapy followed by bleaching.

histologic techniques to study revascularization and wound healing (see Chapter 2).[25] Meyer and colleagues also completed animal studies involving radioactive microsphere methods to quantify preoperative and postoperative blood flow after classic osteotomies.[219] The results of Bell's microangiographic and histologic studies showed minimal transient vascular ischemia, minimal osteonecrosis, and early osseous union, with the maxilla pedicled essentially to the palatal mucosa. *The preservation of the integrity of the descending palatine arteries was not found to be essential to maintain circulation to the down-fractured maxilla.* The periosteal vascular bed provides adequate reserve blood supply after down-fracture, even with ligation of the named vessels. Alteration of the hemodynamics within the intramedullary cavity after total maxillary down-fracture was felt to produce only transient and clinically insignificant intraosseous ischemia (see Chapter 2).

In clinical practice, controversy continues to exist regarding the management of the descending palatine artery (DPA) during Le Fort I osteotomy. Some surgeons advocate the preservation of the DPA, whereas others ligate the vessel routinely. Dodson and colleagues completed a prospective randomized clinical study of patients (N = 34) who underwent Le Fort I osteotomy.[86,87] The individuals were randomly assigned to either Study Group 1 (N = 26), in which the DPA was ligated, or Study Group 2 (N = 18), in

which the DPA was preserved. The researchers measured maxillary gingival blood flow during the operation with the use of a laser Doppler flow meter, and they found "no statistically significant differences in mean maxillary gingival blood flow between patients having the DPA ligated and those having the DPA preserved."[87] The maintenance of adequate flap circulation through the palatal mucosa attached to the hard palate is the key to the avoidance of this problem.

Documented cases of aseptic necrosis after maxillary osteotomies primarily come from the questionnaire survey conducted by **Lanigan and colleagues.**[182] The authors sent out 5000 questionnaires to oral and maxillofacial Surgeons, and 800 replies were received. Fifty-one cases of aseptic necrosis after maxillary surgery were reported from 44 surgeons who had encountered this specific complication. The number of cases reported was assumed to be less than the magnitude of the clinical problem in practice. The results of the questionnaire suggested that, at the time of the survey (i.e., in 1986), a Le Fort I osteotomy performed in multiple segments in conjunction with superior repositioning and transverse expansion (especially when significant palatal perforations occurred) was more likely to result in a tenuous blood supply to the anterior maxilla, with resulting aseptic necrosis. More recently, **Singh and colleagues** described a single patient from the United Kingdom who underwent maxillary Le Fort I osteotomy with down-fracture (without segmentation) and who sustained aseptic necrosis of approximately two thirds of the total maxilla.[305] The patient's risk factors included nicotine abuse, the use of deliberate hypotensive anesthesia in the presence of baseline hypertension, and uncontrolled intraoperative bleeding. In 2010, Pereira and colleagues reported a case of maxillary aseptic necrosis after Le Fort I osteotomy.[255] The patient was 52 years old, with baseline hypertension, an ongoing smoking history of two packs per day, and chronic generalized periodontal bone loss and gingival recession. He underwent Le Fort I down-fracture osteotomy with horizontal advancement. Uncommon bleeding was noticed in the posterior region intraoperatively, and this was treated with gauze compression. On the seventh postoperative day, the researchers reported that the "[m]ucosa overlying the maxilla was ischemic and covered with a pseudomembrane."[255] The patient was treated with 20 sessions of hyperbaric oxygenation. The maxilla and the associated dentition were preserved, but further alveolar bone loss occurred.

Palatal Fistula

The tearing of the palatal mucosa can occur at the time of either surgically assisted rapid palatal expansion (SARPE) or standard parasagittal segmental osteotomies carried out through the Le Fort I down-fracture. A tear is more likely to become clinically apparent when significant transverse expansion is undertaken. Intraoperative palatal mucosa tears at the time of segmental osteotomy will occur and are best managed by meticulous nasal mucosa closure and by interposing a middle layer to limit epithelialization with fistula tract formation during the healing of the palatal mucosa. This can be accomplished with a biocompatible material (e.g., Surgicel, fibrin glue, acellular collagen matrix) that is placed through the down-fractured maxilla directly onto the bony palate (i.e., the floor of nose side) after stabilization of the segments into the prefabricated splint and before the placement of maxillary plate and screw fixation. By instituting precautions to limit pressure gradients across the opening and by avoiding hard food boluses on the roof of the mouth during initial healing, spontaneous closure is typically seen. Under these circumstances, long-term persistent fistulization of a palatal mucosal tear after segmental osteotomies is uncommon. When a palatal (i.e., oronasal) fistula remains and is of clinical concern as a result of a loss of fluid and air, it can be closed with the use of local palatal flaps (Fig. 16-20). Surgical closure should be postponed until 6 to 12 months after Le Fort I osteotomy to ensure adequate maxillary revascularization. During the interim, a custom acrylic palatal plate can be used to both obturate the palatal–nasal opening and to assist with the maintenance of the new arch form.

Fibrous Union (Painless Mobile Maxilla)

The fibrous union of the maxilla after Le Fort I osteotomy is an infrequent complication.[78,162,200,342,350] Risk factors should be recognized, and surgical techniques and postoperative management may then be adjusted to limit this complication. The combination of extensive horizontal advancement and vertical lengthening results in large osteotomy site defects with limited bone contact. Failure to form adequate bony bridges at the healing sites is likely to result in delayed healing, fibrous union, or late relapse. Influences on bone healing at the Le Fort I osteotomy site may include the following: 1) injury to flap circulation 2) thin osteoporotic bone at the buttress and the pyriform rims with inadequate stabilization (fixation) 3) the decision being made to not place interpositional grafts when the bone gaps are of critical size (as described previously) 4) infection or wound dehiscence after surgery 5) the presence of a heavy occlusion (e.g., grinding, clenching) 6) too rapid of a return to normal chewing forces 7) excessive mouth opening against intermaxillary elastics and 8) stress fracture of the fixation plates. Systemic risk factors for poor bone healing include 1) diabetes; 2) collagen disease; 3) vascular disease; 4) osteoporosis and the use of bisphosphonates; 5) nicotine use; 6) poor nutritional status; and 7) prior radiation.

This author has experience with four of his own patients who underwent Le Fort I osteotomy and then developed fibrous union of the maxilla (Fig. 16-21). This represents a small percentage (i.e., <0.5%) of the total group of Le Fort I osteotomies performed. In each case, initial healing seemed unremarkable, with no infection or wound dehiscence. There were no signs of vascular compromise at the time of

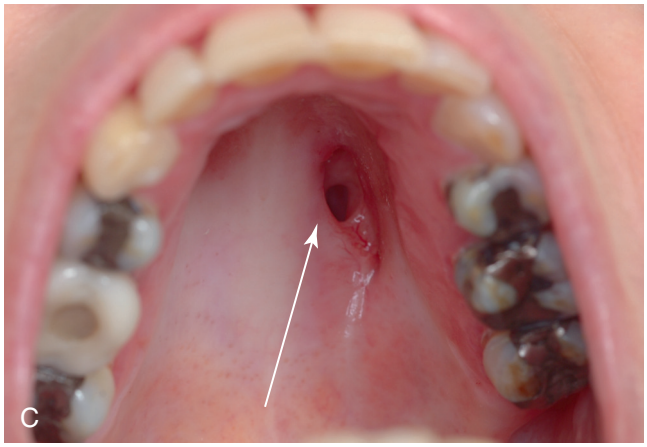
Segmental osteotomies with widening



Palatal fistula early after surgery

Successful surgical closure of fistula

• **Figure 16-20** A 48-year-old woman with a long face growth pattern and Angle Class II anterior open-bite malocclusion is shown. The patient underwent four bicuspid extractions and orthodontic treatment during childhood as a compensatory approach. She was referred by a restorative dentist to an orthodontist and then to this surgeon for evaluation. She was found to have obstructive sleep apnea, chronic obstructive nasal breathing, and a long face growth pattern with a Class II tendency. She underwent a comprehensive surgical, orthodontic, and dental rehabilitative approach. The procedures included maxillary Le Fort I osteotomy in two segments (interdental osteotomy between the central incisors and then parasagitally down the hard palate). The maxillary segmentation was to widen the posterior arch by several millimeters. When placing the maxillary segments into the intermediate splints, a tear in the palatal mucosa at the parasagittal osteotomy location was appreciated. This was managed with Gelfoam and tissue glue through the down-fracture along the floor of the nose and with meticulous nasal mucosa suturing. A fistula persisted at 1 year after surgery, with air loss affecting her speech (i.e., hypernasal speech) and fluid loss occurring into the nose when she was drinking liquids. She underwent outpatient surgery to elevate the palatal flaps, to separate the nasal and palatal mucosa, to suture closed the nasal side, and then to suture closed the palatal side. She was placed on a mechanical soft diet and sinus precautions for 4 weeks. The fistula was successfully closed. **A,** Palatal view before surgery. **B,** Model planning indicating two-segment maxillary osteotomy with widening at the molar region. **C,** Palatal view 1 year after surgery indicating a persistent oronasal fistula. **D,** Palatal view 3 months after the successful surgical closure of the fistula.

• **Figure 16-21** A woman in her mid 40s with an asymmetric mandibular excess growth pattern arrived for surgical evaluation. The longstanding asymmetric Angle Class III negative overjet anterior open-bite malocclusion had been detrimental to her dentition. She required crown restorations and had a need for root canal therapy in several of the posterior teeth. She desired the correction of the malocclusion (i.e., improved chewing and speech articulation) and improved lip closure (i.e., relief of mentalis strain). She had a lifelong history of obstructed nasal breathing and was found to have septal deviation and inferior turbinate enlargement. She agreed to an orthodontic and surgical approach. Orthodontic (dental) decompensation was followed by surgery that included maxillary Le Fort I osteotomy (horizontal advancement, clockwise rotation, and vertical lengthening); bilateral sagittal split ramus osteotomies (asymmetry correction); osseous genioplasty (horizontal advancement); and septoplasty and inferior turbinate reduction. The quality of the maxillary buttress bone was noted to be thin, and it did not hold the fixation plates and screws firmly in all locations as compared with bone of average thickness; however, it was felt to be adequate. No interpositional graft was used, and initial healing was on track. Five weeks after surgery, the patient progressed to a normal diet and her regular physical activities. She also returned to the care of her orthodontist. Postoperative radiographs (lateral cephalometric and Panorex) did not look out of the ordinary. Three months after surgery, during a routine orthodontic evaluation, she was found to have mobility of the maxilla but without pain and with a good occlusion. The diagnosis of fibrous union at the Le Fort I osteotomy site was made. The patient was placed on a liquid diet, told to avoid clenching and heavy biting forces, and asked to stop all use of interarch elastics. Despite a waiting period of an additional 2 months, a painless mobile maxilla (i.e., fibrous union) remained. The patient was returned to the operating room, where she underwent the following:

- Standard circumvestibular incision and subperiosteal anterior maxillary exposure
- Removal of all maxillary fixation plates and screws
- Down-fracture and complete disimpaction
- Removal and cleaning out of all fibrous tissue along the osteotomy sites
- Placement of the maxilla into the preferred occlusion through a prefabricated splint
- Adjustment of the maxilla to the preferred anterior vertical height
- Placement of new titanium bone plates and screws at each zygomatic buttress and pyriform aperture
- Harvesting and crafting of the iliac (hip) corticocancellous graft
- Placement of a bloc graft in each bony gap between the zygomatic buttress and the pyriform plates
- Securing of each graft with an additional titanium microplate and screws
- Packing of additional cancellous bone along the osteotomy sites
- Wound closure

At 5 weeks after surgery with indications of good healing, the patient's diet and physical activities were advanced, and she was returned to her orthodontist's care for maintenance. The appliances were removed 3 months later. **A,** Facial and occlusal views before treatment.

osteotomy or after surgery. None of the patients were felt to have more than average residual mobility at the 5-week postoperative interval upon return to their orthodontist's care. They were then encouraged to gradually return to a regular diet and the usual physical activities as well as to work toward normal mouth opening. The four affected individuals were as follows:

1. *A 15-year-old Caucasian individual with Down syndrome who underwent Le Fort I osteotomy, SSRO of the mandible, and oblique osteotomy of the chin.* The maxilla underwent horizontal advancement and vertical lengthening without interpositional grafting. Maxillary stabilization was performed with a titanium plate placed at each pyriform aperture, and the zygomatic buttress region was secured with screws. The quality of the bone was thin and did not hold the fixation screws as firmly in all locations as is typical. Initial healing was felt to be normal. The patient returned to the orthodontist's care at 5 weeks without special concerns.
2. *A 25-year-old Asian graduate student who presented with congenital facial palsy that resulted in maxillofacial skeletal asymmetry.* This patient underwent Le Fort I osteotomy, SSRO of the mandible, and oblique osteotomy of the chin. The maxilla underwent cant correction and intrusion with minimal horizontal advancement. Stabilization was obtained with a titanium plate placed at each zygomatic buttress, and the pyriform aperture was secured with screws. The quality of the bone was thin and did not hold the fixation screws as firmly at all locations as is typical. Initial healing was felt to be normal. The patient returned to her orthodontist's care at 5 weeks without special concern.
3. *A 45-year-old woman with a history of osteoporosis that had previously been treated with oral bisphosphonates.* This patient's jaw deformity was characterized by maxillary deficiency with relative mandibular excess. She underwent Le Fort I osteotomy, SSRO, and oblique osteotomy of the chin. The maxilla was horizontally advanced and vertically lengthened. Stabilization was performed with a titanium bone plate placed at each zygomatic buttress, and the pyriform aperture was secured with titanium screws. The quality of the bone was thin and did not hold the fixation screws as firmly as is usual at all locations, but it was felt to be adequate. No interpositional graft was placed, and initial healing was felt to be normal. The patient returned to her orthodontist's care at 5 weeks without special concerns.
4. *A 45-year-old woman with an asymmetric mandibular excess growth pattern (see Fig. 18-20).* This patient underwent Le Fort I osteotomy, SSRO, and oblique osteotomy of the chin. The maxilla was horizontally advanced and vertically lengthened. Stabilization was with a titanium plate placed at each pyriform aperture, and the zygomatic buttress was secured with screws. The quality of the bone was thin; it did not hold the fixation screws firmly at all locations as is average, but it was felt to be adequate. No interpositional graft was placed, and initial healing was felt to be normal. The patient returned to her orthodontist's care at 5 weeks without special concerns.

Each of the four patients presented back to this surgeon between 4 and 6 months after surgery complaining of painless but visible motion of the maxilla when clenching and chewing. Each individual presented at that time with a good occlusion and favorable facial aesthetics but with a pain-free mobile maxilla with movement that was observed during compressive occlusal forces. In each case, the patient was placed on a liquid diet and told to avoid clenching and heavy biting forces, and the use of elastics was stopped. Despite a waiting period of an additional 2 months, a painless mobile maxilla (i.e., fibrous union) remained in each case. One of the four individuals elected not to proceed with further surgery and continues to have a painless mobile

maxilla during mastication. The other three patients underwent further maxillary surgery. The procedure included the following steps:

1. Return to the operating room with general anesthesia through standard nasotracheal intubation
2. Maxillary circumvestibular incision and standard subperiosteal dissection for Le Fort I exposure
3. Removal of all maxillary fixation plates and screws
4. Down-fracture and complete disimpaction
5. Removal of all fibrous tissue at the osteotomy sites
6. Placement of the maxilla into the preferred occlusion with the mandibular dentition using a prefabricated splint; adjustment of the maxilla to the preferred vertical height
7. Placement of new titanium plates and screws at each zygomatic buttress and pyriform aperture
8. Harvesting of iliac (hip) corticocancellous graft.
9. Crafting of a corticocancellous (iliac) bloc graft and placement in the bony gaps between the zygomatic buttress and the pyriform plates on each side
10. Securing of each corticocancellous graft with an additional titanium plate and screws
11. Packing of additional cancellous bone along the osteotomy sites
12. Closure of the circumvestibular wound

The three patients who underwent further treatment were maintained on a blenderized diet and placed on limited physical activities for 5 weeks. No intermaxillary fixation and only a limited use of elastics and compression occlusal forces were instituted during this time.

Interestingly, in the three patients who received additional treatment, the fracture of most of the titanium plates was recognized at the time of the redo Le Fort I osteotomy (see Fig. 16-21D). One explanation is that the titanium plate failure occurred soon after surgery. If so, then the fractured plates would be responsible for inadequate immobilization at the osteotomy site, thereby resulting in fibrous union. Another explanation is that bony union did not occur at the usual time (i.e., approximately 4 to 5 weeks after surgery). The initially successful plate and screw fixation masked the fibrous union for several months; this was followed by the eventual stress fracture of the titanium plates in response to the continuous masticatory compressive occlusal forces. Painless mobility of the maxilla eventually became noticeable to the patient (i.e., 4 to 6 months after surgery), and this was then brought to the surgeon's attention.

Despite this author's extensive experience with cleft orthognathic surgery that often requires maxillary segmentation with significant horizontal advancement and vertical lengthening, no cases of fibrous union have occurred in this patient group. The author believes that the routine use of interpositional iliac (hip) grafts placed at the Le Fort I osteotomy site in patients with clefts who are undergoing significant advancement and vertical lengthening is helpful. (This is in addition to the use of titanium plates and screws and a prefabricated splint; the maintenance of a non-chew, liquid diet for 5 weeks; and the absence of postoperative infection or wound dehiscence.)

Acute and Chronic Nasal Obstruction

Buckling and deviation of the nasal septum can occur during the superior repositioning of the maxilla after Le Fort I osteotomy (see Fig. 16-22). When vertically intruding the maxilla, adequate resection of the inferior aspect of the cartilaginous and bony septum is required to avoid this complication.[208] If the septum is properly managed at operation, the occurrence of a "crooked nose" after the removal of the nasotracheal tube should be uncommon. Visual inspection of the nose is necessary after maxillary repositioning just before and again after extubation to confirm that the septum remains straight. If septal displacement is observed after extubation and is simply due to nasotracheal tube pressure, then limited manual manipulation in the recovery room will suffice. If the surgeon did not adequately resect (i.e., manage) the inferior aspect of the septum when completing a Le Fort I intrusion, then a return to the operating room to do so will be required.

The most common reason for persistent postoperative nasal obstruction is preoperative chronic nasal obstruction that was not recognized and addressed (see Chapter 10). The second likely cause of persistent nasal obstruction is inadequate recontouring of the nasal floor, the pyriform rims, and the anterior nasal spine in conjunction with maxillary intrusion.

NOTE: A worsening of any preoperative chronic nasal obstruction in the patient with a long face growth pattern is more likely to occur if the baseline excess anterior nasal floor height is not simultaneously addressed (Fig. 16-22).

Acute and Chronic Maxillary Sinusitis

The occurrence of persistent maxillary sinusitis that requires treatment after Le Fort I osteotomy is not thought to be common, but the true incidence has not been fully studied.[256,374] When maxillary sinusitis after Le Fort I osteotomy does occur, it may be due to the following: 1) changes in the clearance mechanism of sinus mucous; 2) the retention of a blood clot in the sinus cavity; 3) dental infection; 4) the presence of foreign bodies (e.g., grafts, loose fixation devices) in the sinus cavity; or 5) the anatomic blockage of the osteomeatal opening (Fig. 16-23). A blocked ostium can generally be assessed with fiber-optic nasoendoscopy in the office setting. The occurrence of a loose displaced graft that cannot be expressed through the ostium and that then becomes chronically contaminated with bacteria should also be ruled out. A sinus computed tomography scan is helpful to clarify these issues. Standard titanium fixation screws are expected to perforate through the anterior wall into the

• **Figure 16-22** A woman in her mid 30s was diagnosed with a long face growth pattern and mild obstructive sleep apnea. She underwent perioperative orthodontics and orthognathic procedures, including maxillary Le Fort I osteotomy (horizontal advancement and vertical intrusion); bilateral sagittal split osteotomies of the mandible (advancement); and osseous genioplasty (horizontal advancement). The surgery was carried out by another surgeon. Immediately after surgery, in the recovery room, significant asymmetry and distortion of the base of the nose and nasal tip were recognized. Although the patient generally convalesced well, there was persistent obstructed nasal breathing and noticeable nasal base and tip asymmetry and distortion. At 5 weeks after surgery, consultation with this surgeon occurred. Clinical and radiographic examination confirmed uncorrected excess anterior alveolar maxillary height as well as a buckled and deviated quadrangular cartilage. Visually, there was marked distortion of the base of the nose and nasal tip as well as blocked nasal airflow. The patient was taken to the operating room and underwent general anesthesia through orotracheal intubation. A limited intraoral circumvestibular incision was made with the dissection of the anterior maxilla, the floor of the nose, and the anterior aspect of the septum. The maxillary incisal edge to the anterior nasal spine measured 40 mm (elongated by three standard deviations) and confirmed vertical excess. The quadrangular cartilage was buckled and deviated, which further contributed to an obstructed left nasal passage. Using a rotary drill with a watermelon bur and a rongeur, the nasal rims, the floor of the nose, and the anterior nasal spine were recontoured and lowered toward normal morphology. The incisal edge to the anterior nasal spine now measured 30 mm. The inferior aspect of the quadrangular cartilage was resected and repositioned to the midline. **A,** Frontal facial view at 5 weeks after initial surgery indicating distortion and asymmetry of the nasal base and tip. **B,** Intraoperative view of anterior vertically maxillary excess and buckled quadrangular cartilage at redo surgery. **C,** Measurement of the incisal edge to the anterior nasal spine (40 mm) before recontouring confirms the baseline elevation of the nasal floor.

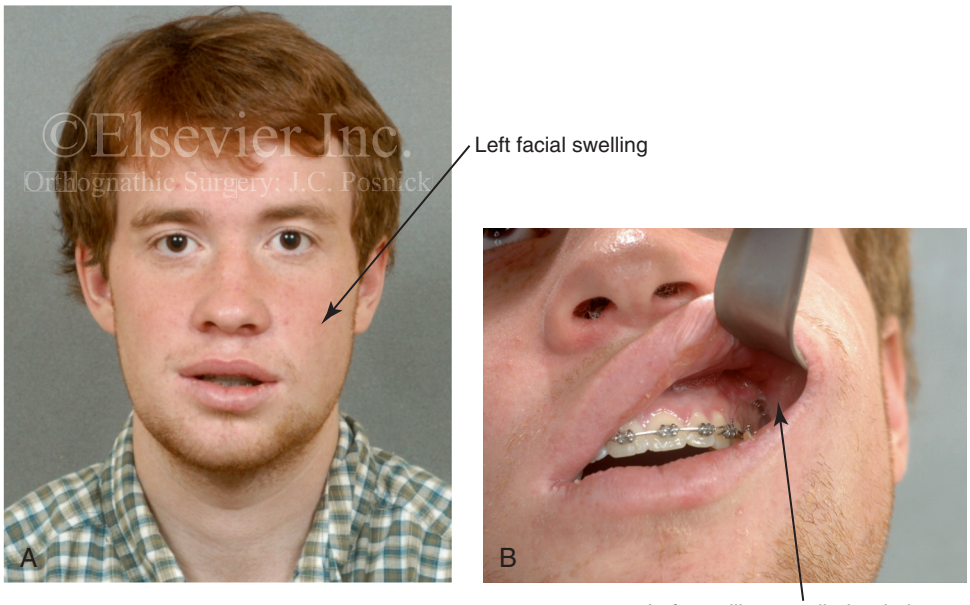
• **Figure 16-22, cont'd H,** Facial views of the patient 5 weeks after the initial orthognathic procedure and then 3 weeks after secondary revision (i.e., recontouring of the floor of the nose and septoplasty). The patient's nose is no longer crooked, and the nasal airway is now patent.



• **Figure 16-23** A 19-year-old man with a maxillary deficiency in combination with asymmetric mandibular excess presented for treatment. He also had chronic obstructed nasal breathing. He was referred for orthodontic and surgical correction. His surgery included maxillary Le Fort I osteotomy (horizontal advancement and clockwise rotation); bilateral sagittal split osteotomies of the mandible (correction of asymmetry); osteotomy of the chin (horizontal advancement); septoplasty; and inferior turbinate reduction. In the presence of a penicillin allergy, prophylactic clindamycin antibiotic was initiated just before surgery and continued for 5 days. Approximately 2 weeks after surgery, left cheek region swelling and intraoral purulent drainage were noted. A computed tomography scan confirmed a fluid-filled left maxillary sinus. The patient was restarted on clindamycin (600 mg by mouth four times daily), and a Penrose drain was inserted into the left maxillary vestibular wound. The cultures confirmed beta-hemolytic streptococci (Group C). Sensitivities indicated that ciprofloxacin was the antibiotic of choice, so the patient was started on a 10-day course. He was also placed on nasal decongestants. Within days, the drainage subsided, and the swelling diminished. The Penrose drain was removed 1 week after insertion. At 5 weeks after surgery, the healing of the osteotomies remained on track, and the patient resumed a regular diet. At 6 weeks, left cheek swelling recurred. A computed tomography scan confirmed a fluid-filled maxillary sinus without adequate drainage into the nose. Nasoendoscopy confirmed a blocked ostium. The endoscope was used to create an ostium to drain the sinus. No further sequelae occurred. **A,** Frontal facial view 2 weeks after surgery showing left cheek swelling. **B,** Left maxillary vestibular wound indicating the site of drainage.

sinus. They are often presumed to be the source of sinusitis; however, this author's experience, that is rarely the case. Interestingly, the most common reason for postoperative chronic sinusitis is preoperative chronic sinusitis that was not recognized and addressed.

The entity of a surgical *ciliated cyst* has been reported after elective orthognathic procedures. These cysts are typically lined with respiratory epithelium. The pathogenesis is hypothesized to involve antral mucosa that is exposed at the time of Le Fort I osteotomy. If the cyst is located in the soft tissues, the displaced mucosa will have been "trapped" in the surgical wound. When the cyst is located in the antrum, then the etiology is thought to be disrupted mucosa trapped in the sinus behind a closed ostium.

Risks and Complications Specific to the Oblique Osteotomy of the Chin (see Chapter 38)

Infection

Infection occurs in less than 1% of patients who are undergoing osseous genioplasty. The routine use of prophylactic antibiotics to cover both oral flora and skin organisms is useful for the limiting of this complication. If an implant is placed to augment the chin (rather than a chin osteotomy being performed) a higher rate of infection is expected.

Mental Nerve Injury

The mental nerve is at risk for injury in association with an osseous genioplasty.[114,238,349] When the soft-tissue dissection and retraction carried out for the exposure of the chin are carefully completed, the mental nerves will be stretched but rarely lacerated or avulsed. If this is the case, the observed immediate loss of sensibility in the lip and chin region should be temporary. The mental nerve can be cut during the soft-tissue incision. Care is taken with the lateral aspect of the incision to avoid this problem. The nerve can be stretched excessively or avulsed from the mental foramen during retraction at the time of osteotomy (see Chapter 15). It is important to remember that the nerve dips below the mental foramen posteriorly. The nerve also extends anteriorly (i.e., the incisal nerve) and may be injured in this location. After genioplasty, approximately 10% of patients will experience a degree of permanent loss of sensibility in the distribution of the mental nerve on one or both sides.

Wound Complications

The osseous genioplasty is completed through an intraoral vestibular incision.[63] To limit wound-healing difficulties, the incision should be made in the depth of the vestibule. The maintenance of a thick cuff of mucosa and muscle tissue adjacent to the cervical margins of the teeth for a relaxed wound closure in two layers (i.e., muscle and mucosa) limits wound dehiscence, muscle dysfunction, chin ptosis, and long-term mucogingival problems. Placing the soft-tissue incision too high in the vestibule can negatively affect wound closure, thereby resulting in dehiscence or scar bands with periodontal sequelae (i.e., mucogingival pull) (Videos 11 and 12).

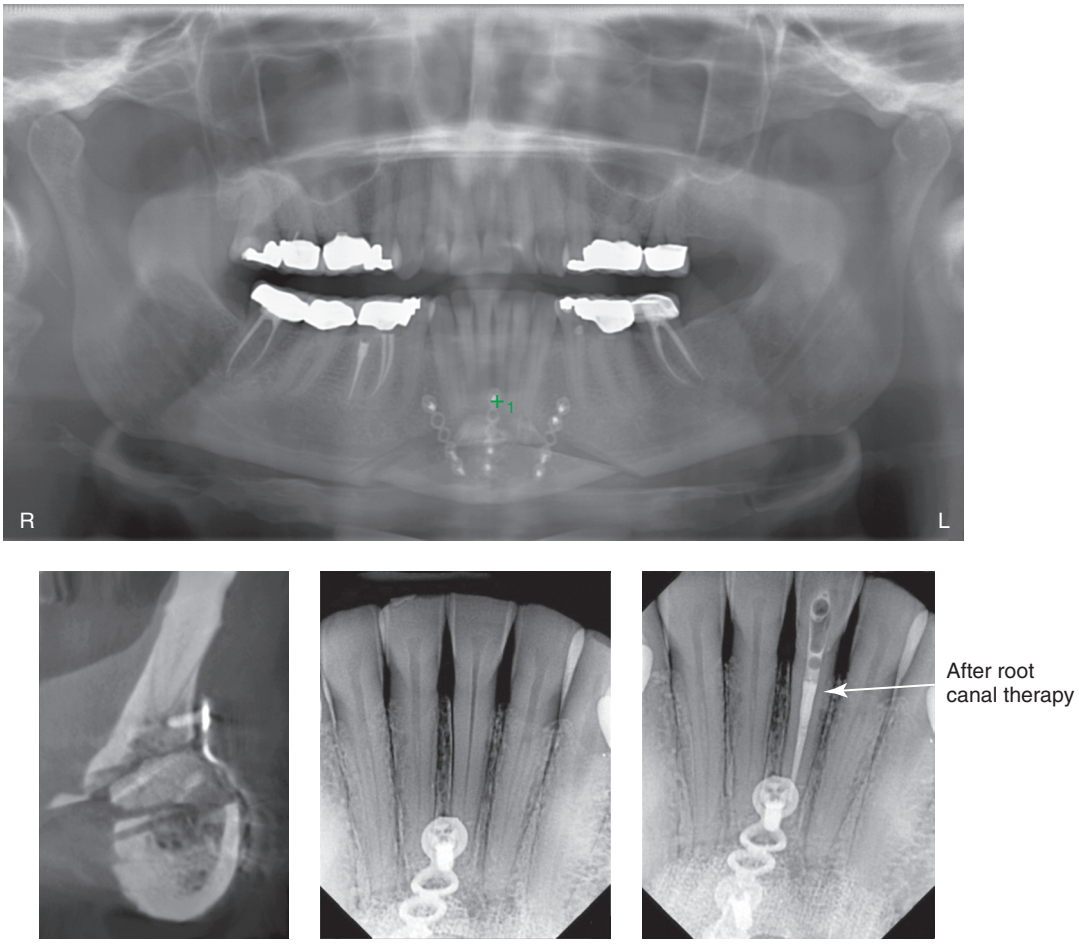
Injury to the Teeth

The location of the chin osteotomy should be based on the patient's chin dysmorphology and a review of the radiographs of the anterior teeth. Injury to the teeth at the time of osteotomy should be an uncommon occurrence. Dental injury may also occur from the fixation screws. If a dental injury is sustained, evaluation by the patient's dentist, referral to an endodontist, and a discussion between the surgeon and the patient are essential, because root canal therapy and other forms of treatment may be indicated (Fig. 16-24).

Suboptimal Facial Aesthetics

Patient dissatisfaction after an osseous genioplasty may relate to facial aesthetics. This is best avoided by doing the following:

1. Having a detailed discussion with the patient concerning his or her objectives and reviewing the patient's overall pretreatment facial and chin morphology and aesthetics (i.e., the recognition of any associated dentofacial deformity) as well as any presenting head and neck dysfunction (e.g., lip incompetence, mentalis strain, obstructive sleep apnea)



• **Figure 16-24** An osseous genioplasty was carried out for the vertical lengthening (interpositional graft) and horizontal advancement of the chin. Postoperative radiographs indicate the closeness of screw fixation (1.7 mm wide and 4 mm in length) to the lateral incisor but without root resorption. The darkening of the crown indicated pulpal injury. Root canal therapy and internal bleaching were carried out.

2. Making sure that there is a clear understanding between the surgeon and the patient with regard to the operative objectives and any compromises in treatment
3. Having the surgeon meticulously execute the procedures with the patient under controlled anesthesia and with competent assistance and proper instrumentation
4. Having the surgeon perform an objective assessment and then discussing with the patient the results achieved and any shortcomings perceived

Conclusions

No matter how accurate the diagnosis, how comprehensive the approach, and how meticulous the surgical technique, complications will occur in a small percentage of patients after orthognathic surgery. Through the discussion of the spectrum of procedure-specific complications and their biologic basis, informed decisions can be jointly agreed to every step of the way by the surgeon, the patient, and the patient's family.

Patient Education Materials

Coordination of Orthodontics and Orthognathic Surgery

To achieve optimal occlusion and facial aesthetics, individuals with jaw discrepancies benefit from a comprehensive coordinated orthodontic and surgical approach.

The goals of orthodontics in preparation for jaw surgery will be distinctly different from those of orthodontic "camouflage" treatment of a skeletal malocclusion. Orthodontic camouflage occurs when your orthodontist attempts to pull the upper and lower teeth together even though the jaws are far apart. Over the long term, this may cause periodontal problems, including the loss of the bone and gingiva surrounding the teeth. In any case, orthodontic camouflage does not correct the jaw deformity or its associated dysfunctions and facial aesthetic concerns. To fully evaluate your needs, your surgeon will likely suggest consultation visits with a speech pathologist and an ear, nose, and throat surgeon. He or she may also recommend evaluation by other medical or dental specialists.

For these reasons, it is important for you to make an educated decision (i.e., orthodontics and jaw-straightening surgery versus orthodontic camouflage treatment alone) before you begin orthodontic treatment. Attempting to correct a jaw problem orthodontically with surgery held out as a contingency plan may result in extended orthodontic treatment time, and it is likely to compromise long-term dental health and facial appearance.

The coordination of orthodontic treatment and jaw surgery from the beginning provides the best opportunity to help you to achieve long-term dental (periodontal) health, efficiency of treatment time, and preferred facial aesthetics. A benchmark time frame for the achievement of the presurgical goals can be set in advance. After you make the decision to proceed, you may wish to contact your medical insurance carrier to determine its commitment for the expected procedures. Our office will work with you toward that end.

For most individuals, good interdigitation of the upper and lower teeth (i.e., occlusion) at the time of surgery requires that specific orthodontic objectives be met. The presurgery orthodontic goals may include the following:

- The correction of dental rotations, anteroposterior misalignments, spacing, and crowding
- The proper torquing of the anterior teeth to achieve ideal dental inclination
- The closure of extraction spaces (unless this is to be achieved by "segmenting" the jaw during surgery)
- The coordination of the dental arch width (unless this is to be achieved by "segmenting" the jaw during surgery)
- The leveling of the occlusal plane or curve of Spee (unless this is to be achieved by "segmenting" the jaw during surgery)

Orthodontic appliances (i.e., braces) are necessary for both presurgical and postsurgical tooth movement as well as to stabilize the jaws during and after surgery. The orthodontic wire sequence is accomplished by the orthodontist at interval visits before surgery. This will preferably end with full-dimensional steel stabilization wires. These passive surgical wires in each arch (i.e., the upper and lower teeth) will prevent any further movement of the teeth just before and during surgery.

The stabilizing passive surgical wires will be placed by your orthodontist approximately 2 to 6 weeks before the date of surgery and only after sufficient presurgical orthodontic objectives are met. Closer to the date of surgery, your orthodontist will also place interdental hooks on the stabilizing wires to meet surgical and early postsurgical needs.

Continued

After the passive surgical wires are in place, your surgeon will obtain the immediate presurgical records, which include alginate impressions of the teeth, centric bite registration, face-bow registration, and facial measurements. The dental casts are generally mounted on a semi-adjustable articulator for the completion of surgical planning and splint construction. Information from the surgical planning will be used during the operation to achieve the most precise occlusion and preferred facial aesthetics.

Orthognathic surgery is performed in an operating room with the use of general anesthesia. Before surgery, you should undergo a physical examination by your general physician and obtain necessary laboratory work to ensure your safety. You will check into the hospital on the morning of your surgery, and the operation will generally take from 2 to 4 hours, depending on surgical details. The length of hospital stay is generally 1 to 2 nights.

During the initial recovery period, you can expect swelling (especially of the lips and cheeks), and this will be followed by bruising. The swelling is progressive during the initial 24 to 48 hours after surgery. Nasal congestion, a sore throat, and varying degrees of nausea should also be anticipated. Medications are prescribed to limit these issues. During surgery, the sectioned facial bones are secured back together in their new location with the use of small titanium plates and screws. The use of these plates and screws is a technical advance that limits the need for wiring the jaws together. Instead, orthodontic elastic bands will be used intermittently after surgery and for several weeks after to allow the jaws to comfortably rest together, as needed. The orthodontic elastic bands can be removed at any time, if need be.

Prescriptions for liquid pain medication and antibiotics will be given for use after you leave the hospital. We will advise you about maintaining a high-protein blenderized diet, the importance of adequate hydration, and necessary limitations of your physical activities.

In general, after you leave the hospital, you will be asked to basically remain at home for the initial 2 weeks. Ambulation (walking) is encouraged, and you may read and complete desk-type work as you wish. Returning to "basic" office work or school after 2 weeks is the general rule, but you must refrain from physical activities (e.g., exercise, sports) for a total of 5 weeks.

Although the initial healing phase will generally take approximately 5 weeks to occur, the completion of the healing process will require 6 to 12 months. In general, your orthodontist will begin the postsurgical phase of orthodontic treatment 5 weeks after surgery to maintain the result and to fine-tune your bite. Braces are generally removed within 6 months after surgery, but this will vary in accordance with your individual needs.

As with any operation, certain side effects and complications are possible. Complications specific to orthognathic surgery may be those related to anesthesia, infection, bleeding, alterations in facial sensibility, injury to adjacent teeth or bones, relapse of the new jaw position with malocclusion, limited range of lower jaw movement, temporomandibular (jaw) joint dysfunction, and suboptimal facial appearance. Fortunately, most of these complications are rare; however, the relative risks for your specific surgery should be discussed and understood before proceeding. A separate and detailed consent form will also be provided.

Orthognathic (jaw-straightening) surgery in combination with orthodontics will generally move your teeth and jaws into a new position that is more balanced, functional, and healthy. For a successful outcome, communication is essential. Your orthodontist and surgeon will work together and respond to your concerns. We look forward to providing the highest-quality medical, dental, and facial care to you.

Jeffrey C. Posnick, DMD, MD
Director, Posnick Center for Facial Plastic Surgery

Consent for Orthognathic Surgery

_____ **INSTRUCTIONS**

Initial here This is a document that has been prepared to help your surgeon to educate and inform you about your orthognathic (jaw) surgery and its risks as well as alternative treatment options. It is important that you read this document carefully and completely. Please initial each section on each page to indicate that you have read and understand it. In addition, please sign the consent for surgery on the last page as proposed by your surgeon.

_____ **INTRODUCTION**

Initial here Orthognathic surgery is carried out in conjunction with orthodontic treatment. In general, this is for the purpose of aligning the teeth, improving the occlusion (bite), and enhancing the facial appearance. For most patients, the improvement of speech articulation, breathing, swallowing, and ease of lip closure are additional benefits. Whether or not these would be expected benefits for you should be discussed with your surgeon.

From start to finish, the process generally requires 1 to 2 years, with the majority of orthodontic treatment being carried out before the surgical procedure. The braces remain on the teeth at the time of operation. After surgery, orthodontic treatment continues for the purposes of maintaining the result and detailing the bite.

As your presurgical orthodontic treatment nears completion, additional dental and facial records will be taken. Your surgeon will use articulated dental models to simulate surgery and to more precisely achieve the desired occlusion and facial aesthetics for you in the operating room. From these models, an acrylic bite wafer (splint) will be made to serve as a guide during surgery for the tooth and jaw alignment that we hope to achieve.

Orthognathic surgery is performed in a hospital operating room with the use of general anesthesia. The operation will generally take from 2 to 4 hours, depending on your individual surgical details. The length of the hospital stay is generally 1 or 2 nights.

Orthognathic surgery is an art and a science, but it is not magic. The procedures are individualized for each patient, and the results depend on the characteristics and quality of your tissues (i.e., bones, muscles, skin, teeth, temporomandibular joints, mucosa) and on complicated biologic factors (e.g., tissue deficiencies, effects of previous treatments). The best candidates for orthognathic surgery are those individuals who require and who are interested in making improvements to their occlusion their long-term dental health, their upper airway (breathing), and their facial aesthetics. These patients are looking for enhancements in one or more of these areas but do not expect perfection; they have realistic expectations, they understand the potential risks, and they are psychologically stable.

_____ **ALTERNATIVE TREATMENTS**

Initial here Alternative forms of management include not undergoing orthognathic surgery at all or possibly proceeding with other, more limited surgical options. These alternatives should be understood and discussed to your satisfaction before proceeding. In some circumstances, individuals may choose an orthodontic "camouflage" treatment option or restorative dental procedures to alter the occlusion, even though the skeletal (jaw) deformity will remain. Risks and potential complications are also associated with these alternative forms of treatment. These are all issues to consider in detail before you select the option that best suits your overall needs.

_____ **RISKS OF SURGERY**

Initial here Every surgical procedure involves a certain amount of risk. An individual's choice to undergo a procedure is based on the comparison of the risk to the potential benefit. Although the majority of patients do not experience the complications detailed below, you should discuss each of these items with your surgeon. Be sure that you understand the risks, potential complications, and consequences of the orthognathic and facial procedures that are planned for you.

Continued

_____ **SURGICAL ANESTHESIA**

Initial here Both local and general anesthesia involve risk. There is a possibility of complications, injury, and even death from all forms of surgery as well as from surgical anesthesia or sedation. At your request, a presurgical consultation visit with the anesthesiologist can be arranged to review these issues in detail.

_____ **AIRWAY COMPROMISE**

Initial here Compromise of the airway in association with orthognathic surgery may occur: at the time of the induction of anesthesia; during the surgical procedure; early after surgery before hospital discharge; or later during convalescence at home. With a skilled and experienced team (i.e., the surgeon, the anesthesiologist, and the hospital staff), close patient supervision (i.e., by family and friends), and cooperation after discharge, the risk of airway compromise can be minimized every step of the way.

_____ **INFECTION**

Initial here Infection is infrequent after orthognathic surgery. Prophylactic antibiotics that are started just before surgery and continued during hospitalization and after discharge will be given. If an infection does occur, additional treatment (e.g., a change in antibiotics, drainage and other procedures) may be necessary.

_____ **SCARRING**

Initial here Although good healing after the surgical procedure is expected, less than ideal healing including unattractive scars may occur within the skin, the deeper structures, and the mucous membranes. Additional treatment, including surgical procedures, may be helpful to manage any scarring.

_____ **BLEEDING**

Initial here The use of hypotensive anesthesia techniques has greatly diminished the need for blood transfusions during orthognathic surgery. The decision about when to transfuse will be dependent on a combination of your physiologic parameters. The need for blood replacement should not be considered a complication but rather a consequence of the orthognathic procedures in a small percentage of patients (approximately 5%). In rare instances, excessive hemorrhage may occur that requires either ligation of the involved blood vessel or selective embolization. Ask your surgeon for more information about the limited need for blood transfusions during orthognathic surgery.

_____ **ALTERATION OF FACIAL SENSIBILITY AS A RESULT OF UPPER JAW SURGERY**

Initial here With upper jaw surgery (i.e., Le Fort I osteotomy), the infraorbital nerve is at risk for injury. As a result, the skin of the cheek, the side of the nose, the upper lip, the gingiva (gums), and the mucosa of the roof of the mouth (palate) will have diminished feeling. Gradually over the course of 6 to 12 months, the feeling improves and generally returns towards normal. This should not be considered a complication but rather a consequence of the procedure. Ask your surgeon for more information about facial sensory loss associated with upper jaw surgery.

_____ **ALTERATION OF FACIAL SENSIBILITY AS A RESULT OF LOWER JAW SURGERY**

Initial here With lower jaw surgery (i.e., sagittal ramus osteotomies), the inferior alveolar nerve is at risk for injury; with reshaping of the chin (i.e., osseous genioplasty), the mental nerve is at risk. This will result in diminished sensation of the lower anterior teeth and gums, the lower lip, and the skin of the chin region. Gradually over the course of 6 to 12 months, the feeling improves, but it does not fully return to normal. The degree of permanent diminished sensation and how it is interpreted is unique to the individual and not entirely predictable. This should not be considered a complication but rather a consequence of the procedure. In rare cases, lower jaw surgery may result in altered sensation and taste ability of the tongue (i.e. lingual nerve). Ask your surgeon for more information about facial sensory loss associated with lower jaw surgery.

_____ **INJURY TO TEETH AND BONE**

Initial here During the orthognathic procedures, adequate circulation to each of the dental and bone segments must be maintained for satisfactory healing. Direct injury to the roots of the teeth or interruption of the circulation to the bone segments can occur. If so, loss of bone is possible. Injury to the teeth (i.e., devitalization) that requires treatment with a root canal is also possible. Additional potential complications include unplanned bone fractures (i.e., fragmentation), delayed healing, sinus obstruction, or openings from the roof of the mouth into either the sinus cavity or nose (i.e., fistulas). These are not common events, but they must be mentioned as possible occurrences.

_____ **FIXATION HARDWARE**

Initial here The use of titanium plate and screw fixation has greatly improved the results of orthognathic surgery and diminished complications such as infection, malocclusion, and relapse. After the jaw bones have healed in their new locations, the plates and screws are no longer needed. In general, however, they are not routinely removed. In approximately 5% of individuals, one or more of the plates or screws may eventually be of concern. If so, these can be removed after healing has occurred. In rare cases, a fixation screw may injure a tooth. If so, the injured tooth may require root canal therapy or even extraction.

_____ **RELAPSE OF THE NEW JAW POSITION**

Initial here With the use of plate and screw fixation across each osteotomy site, unmanageable degrees of relapse (i.e., the return of the jaws toward their preoperative locations) have become much less frequent. Nevertheless, remodeling at the osteotomy sites and of the condylar heads (i.e., the jaw joints) may occur, especially during the initial 6 to 12 months after surgery. When this happens, varying degrees of relapse can occur. Suboptimal occlusion that is appreciated early after the operation is also possible. In some cases, further jaw growth may occur after treatment, which will result in recurrent malocclusion. Despite the potential for these problems, the need for revision osteotomies (i.e., redo jaw surgery) is not frequent.

_____ **TEMPOROMANDIBULAR JOINT PAIN OR DEGENERATION**

Initial here An individual with a jaw deformity and malocclusion may be at greater than average risk for baseline temporomandibular (jaw) joint problems (i.e., pain, popping, clicking, locking, and limited range of motion) as compared with the general population. Orthodontic treatment, restorative dentistry, and orthognathic surgery carried out to improve occlusion should be considered somewhat unpredictable with regard to their overall effect on preexisting temporomandibular joint dysfunction. For some, temporomandibular joint complaints will diminish and function will improve, whereas for others these issues may worsen or not change at all as a result of treatment (e.g. orthodontics, restorative dentistry, orthognathic surgery). Progressive condylar (jaw joint) reabsorption (i.e., the melting away of the bone) is an infrequent cause of relapse after orthodontic treatment and orthognathic surgery. When it does occur, malocclusion results, and further treatment may be required. Ask your surgeon for more information about this rare condition (i.e., idiopathic condylar resorption).

_____ **FACIAL PAIN**

Initial here Individuals with jaw deformities and malocclusion may be at higher risk for baseline facial pain than the general population. The effects of jaw surgery should be considered somewhat unpredictable with regard to their overall effect on facial pain. The changes in occlusion (bite) and altered facial sensation as a result of the jaw surgery are interpreted differently by each individual. For a small percentage of patients (approximately 5%), facial pain or discomfort (i.e., dysesthesia) is persistent and bothersome. Additional treatment or surgery may be possible should facial pain or discomfort persist.

Continued

_____ **DISSATISFACTION WITH FACIAL APPEARANCE**

Initial here An individual may feel dissatisfied with the overall facial appearance achieved after orthodontics and orthognathic (facial) surgery. Despite your surgeon's best efforts, on occasion, this type of surgery can result in visible deformities, loss of function, or structural malposition. You may be disappointed if the results of treatment (e.g., restorative dentistry, orthodontics, orthognathic and facial surgery) do not meet your expectations. Additional treatments and procedures may be possible should the results be suboptimal for you.

_____ **FACIAL ASYMMETRY**

Initial here The human face is normally asymmetric. This asymmetry may be in the upper or lower aspects of the face. It may be in the soft tissues, the skeleton, or both. There can be variations from one side of the face to the other with regard to the results achieved with orthognathic and facial procedures. Additional surgery may be possible should the extent of asymmetry be of concern to you.

_____ **INTRANASAL SURGERY**

Initial here For some individuals, the shape, position and size of the septum of the nose (i.e., the dividing wall between the left and right nasal passages) or the inferior turbinates (i.e., specific structures inside the nose) can interfere with nasal breathing, sinus drainage, or both. When septoplasty (i.e., the removal of bone and cartilage from the septum) and inferior turbinate reduction (i.e., the removal of part of the turbinate) procedures are carried out with a goal of improving breathing and sinus drainage, it is possible that you may experience problems such as bleeding or continued difficulties with the airway and sinus function. There is also the possibility that the septal surgery will cause a perforation (i.e. opening) between the nasal passages to develop. Fortunately, occurrences of these complications are not common. Despite your surgeon's best efforts, a septoplasty or an inferior turbinate operation may not fully achieve the desired result. In some cases, additional treatment or surgery may be helpful to resolve these residual problems.

_____ **REMOVAL OF WISDOM AND OTHER TEETH**

Initial here The extraction of teeth is an irreversible process. As with any surgery, there are associated risks. For example, infection may occur, despite the use of prophylactic antibiotics. Possible damage to adjacent teeth is another concern, especially for those teeth with large fillings or caps. Numbness or altered sensations of the teeth, gums, lips, tongue, and chin may occur as a result of the closeness of the tooth roots to the nerves, which can be bruised or damaged. The incomplete removal of tooth fragments (i.e., small root tips) may be necessary to avoid injury to vital structures such as the nerves or the sinus. A sinus opening or perforation that requires further treatment may occur with the removal of an upper wisdom tooth. Most procedures to remove wisdom teeth are routine. and serious complications are not expected.

_____ **MEDICATIONS**

Initial here Medications, drugs, anesthetics, and prescriptions may cause drowsiness and a lack of awareness and coordination, which can be increased by the use of alcohol or other drugs. Your surgeon advises you not to operate any vehicles, automobiles, or other potentially hazardous devices for 4 weeks after orthognathic surgery and then only after approval is given.

CONSENT FOR ORTHOGNATHIC SURGERY

1. I hereby authorize my surgeon, _____, and such assistants as may be selected by my surgeon to perform the following procedure(s):

   _____

   _____

   _____

   _____

2. I have received, read, and understand the following information sheets:
   - Consent for Orthognathic Surgery
   - Coordination of Orthodontics and Orthognathic Surgery
   - Patient Instructions for Orthognathic Surgery
3. I recognize that, during the course of the operation, unforeseen conditions may necessitate different procedures than those listed above. I therefore authorize my surgeon, _____, and my surgeon's assistants or designees to perform such other procedures that are in the exercise of professional judgment necessary and desirable. The authority granted under this paragraph shall include all conditions that require treatment and that are not known to my surgeon at the time the operation is begun.
4. It has been explained to me that, during the initial healing phase after surgery, I will be using orthodontic rubber bands (elastics) that position my upper and lower teeth together. I agree to be familiar with how to remove the rubber bands. I understand that I may remove the rubber bands at any time if I feel the need to do so.
5. I acknowledge that no guarantee has been given by anyone with regard to the results that may be achieved by the procedures to be carried out.
6. I agree not to use alcoholic beverages and unprescribed drugs, and I have been advised to avoid all sports and water activities for at least 5 (five) weeks and then to resume them only after approval by my surgeon.
7. I agree not to use nicotine or nicotine products for at least 3 weeks before and 2 weeks after surgery.
8. I consent to the photographing of me (head and neck region) before, during, and after surgery. These photographs may be used by my surgeon for medical, scientific, or educational purposes now and in the future.
9. I have provided my surgeon, _____, with all of my past and current medical and dental information. I agree to cooperate completely with all recommendations while I am under my surgeon's care, and I realize that not doing so could result in a less than optimal result.
10. I consent to the disposal of any body tissues or medical devices that may be removed.
11. **THE FOLLOWING INFORMATION HAS BEEN EXPLAINED TO ME IN A WAY THAT I UNDERSTAND:**
    - **THE PREVIOUSLY DESCRIBED PROCEDURES TO BE UNDERTAKEN**
    - **ALTERNATIVE PROCEDURES AND METHODS OF TREATMENT THAT I HAVE DECIDED AGAINST**
    - **THE SPECIFIC RISKS AND POTENTIAL COMPLICATIONS OF THE PROCEDURES THAT I PLAN TO UNDERGO**

I CONSENT TO THE PROCEDURES AND THE ABOVE LISTED ITEMS (1 THROUGH 11). I AM SATISFIED WITH THE EXPLANATION GIVEN TO ME.

Malocclusion after Orthodontics and Orthognathic Surgery: Prevention and Treatment Pitfalls

JEFFREY C. POSNICK, DMD, MD

- Sagittal Split Ramus Osteotomies of the Mandible: Skeletal Stability and Relapse
- Le Fort I Osteotomy: Skeletal Stability and Relapse
- Orthodontic Treatment: Dental Stability and Relapse
- Management of Transverse Maxillary Deficiency: Techniques and Relapse Patterns
- Conclusions

There are inherent limitations to the orthodontic movement of teeth and the surgical repositioning of the jaws and jaw segments; these limitations are imposed by the alveolar bone and the periodontium, the overlying soft-tissue envelope, the masticatory and facial musculature that surrounds the maxillomandibular skeleton, and the temporomandibular joints. If the biologic boundaries are not respected during the movement of teeth, and the surgical repositioning of the jaws, malocclusion is one potential adverse consequence that may follow. The vector changes of the jaws, the jaw segments, and the teeth that are more prone to relapse are known, and so are many of the reasons why. The intent of this chapter is to review the most prevalent causes of malocclusion after osteotomies used to reposition the jaws and orthodontic mechanics used for the movement of teeth in the correction of dentofacial deformities.

Sagittal Split Ramus Osteotomies of the Mandible: Skeletal Stability and Relapse

Immediate (Early) Malocclusion after Sagittal Split Ramus Osteotomies

An immediate (early) malocclusion that is recognized either intraoperatively or soon after surgery (i.e., during the first several days or weeks afterward) will occur after sagittal split ramus osteotomies of the mandible unless each of the following intraoperative conditions is met* (Figs. 17-1 through 17-4):

1. The proximal segment is successfully split from the distal mandible (i.e., no "bad" split) on each side (right and left).
2. The distal mandible is placed in the preferred occlusion and tightly held in intermaxillary fixation (IMF). Unless the natural occlusion between the upper and lower teeth is precise (i.e., without centric relation–centric occlusion slides), the IMF should be maintained with the use of an accurate prefabricated acrylic splint.
3. Each proximal segment is positioned with the condyle seated in the terminal hinge position. Each proximal segment is then secured to the distal segment with the use of either passively placed bicortical screws or monocortical screws and plates. This is accomplished without torquing or overseating the proximal segment. The following conditions should be present:

• **Figure 17-1** A woman in her late 20s was referred by her orthodontist for surgical evaluation. She suffered with masticatory muscle discomfort while chewing and had a jaw deformity, malocclusion, and a lifelong history of obstructed nasal breathing. A long face Class II growth pattern was evident from her childhood onward. She had undergone attempted orthodontic growth modification and then a camouflage approach, without success. She then underwent orthodontics (including upper bicuspid extractions) and surgery at another institution; this included a Le Fort I osteotomy and bilateral ramus osteotomies. Analysis confirmed both inadequate positioning of the jaws at the time of operation and then dental relapse of the maxillary arch form over time. When she presented to this surgeon, her clinical problems included the following:

- TMD with masticatory muscle discomfort
- Maxillary deformity (transverse constriction, vertical excess, horizontal deficiency, and clockwise rotation)
- Mandibular deformity (horizontal retrusion and clockwise rotation)
- Chin deformity (excess vertical length and horizontal retrusion)
- Obstructed nasal airway (septal deviation, high nasal floor, constricted aperture, and inferior turbinate enlargement)

The patient was treated for temporomandibular disorder and then with a comprehensive orthodontic and surgical approach. Splint therapy was useful to relieve masticatory muscle comfort, and orthodontic dental decompensation was then carried out over approximately 12 months. Her surgery included maxillary Le Fort I osteotomy in segments (horizontal advancement, vertical intrusion, counterclockwise rotation, and transverse widening); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical reduction and horizontal advancement); and septoplasty, inferior turbinate reduction, and recontouring of the nasal floor. After initial healing and splint removal (i.e., 5 weeks after surgery), orthodontic maintenance and detailing continued for 9 months. **A,** Frontal and occlusal views before retreatment. **B,** Profile and cephalometric views before retreatment.

• **Figure 17-2** A man with a developmental jaw deformity that was characterized as an asymmetric mandibular excess growth pattern (i.e., hemimandibular elongation) presented for treatment. His orthodontist originally attempted growth modification followed by orthodontic camouflage that included four bicuspid extractions, without success. When he was 19 years old, the patient underwent further orthodontics and a surgical approach at another institution. His jaw surgery at the time included maxillary Le Fort I osteotomy and bilateral vertical oblique ramus osteotomies. An initial satisfactory surgical result was not achieved, and further orthodontic camouflage was attempted. During ongoing orthodontic treatment, alveolar bone loss and gingival recession occurred along the buccal aspect of the posterior maxillary dentition and the labial aspect of the anterior mandibular dentition. At the time of referral to this surgeon, the patient was 35 years old; thus, it had been 16 years since his suboptimal treatment. Evaluations were arranged with a periodontist; an orthodontist; a speech therapist; and an ear, nose, and throat specialist. After periodontal treatment, orthodontic decompensation was carried out in preparation for reconstruction. The patient's surgery included maxillary Le Fort I osteotomy in segments (cant correction, transverse expansion, and minimal horizontal advancement); sagittal split ramus osteotomies (asymmetry correction and minimal horizontal advancement); osseous genioplasty (vertical reduction and horizontal advancement); and septoplasty and inferior turbinate reduction. **A,** Frontal and occlusal views before retreatment. **B,** Current profile view shown next to a lateral cephalometric radiograph taken before original surgery, when the patient was 19 years old.

• **Figure 17-3** A 28-year-old woman was referred by her orthodontist for the evaluation of residual malocclusion and facial asymmetry. Eight years earlier, the patient had presented with an asymmetric mandibular excess growth pattern and underwent a combined orthodontic and surgical approach at another institution. The surgery included maxillary Le Fort I osteotomy (three segments) with iliac interpositional grafting in combination with bilateral sagittal split ramus osteotomies. Immediately after surgery, the occlusion that had been achieved was recognized to be unsatisfactory. The patient was taken back to the operating room 1 week later for the removal of the fixation of the right ramus of the mandible, the adjustment of the occlusion, and the reapplication of fixation. The occlusion remained unsatisfactory. Six months later, the patient was taken back to the operating room again, where she underwent a left vertical oblique ramus osteotomy without fixation followed by 6 weeks of intermaxillary fixation. Over the long term, the occlusion remained unsatisfactory, and the patient also had a minor degree of facial asymmetry as seen in the frontal view. At the time of referral to this surgeon, the patient stated that she hoped for the correction of the occlusion and an improvement in her current lip asymmetry. The decision was made to not operate on the mandible again. Options to improve the occlusion included maxillary Le Fort I osteotomy in segments versus surgically assisted rapid palatal expansion. Segmental maxillary surgery with immediate repositioning and interpositional grafting was carried out. The occlusion was maintained with a prefabricated acrylic splint for 6 weeks, which was followed by the immediate placement of a transpalatal arch. **A,** Frontal facial and occlusal views before retreatment. **B,** Profile facial view and lateral cephalometric radiograph before retreatment.

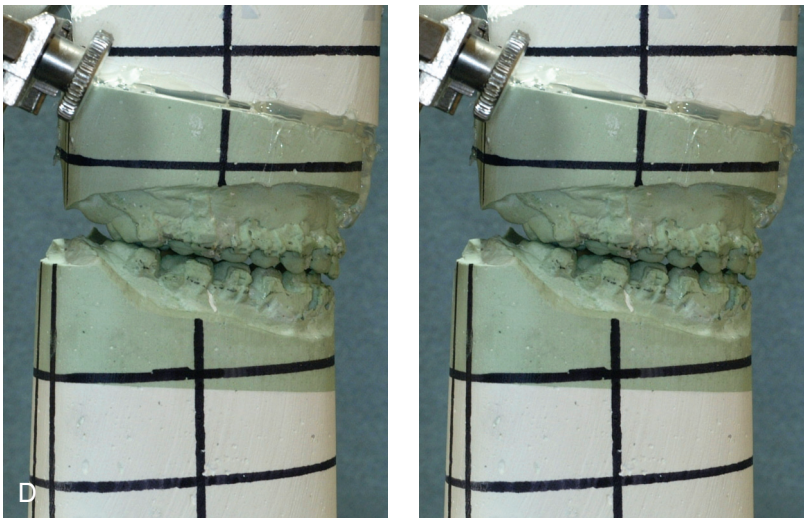
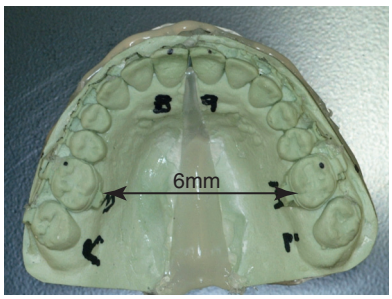
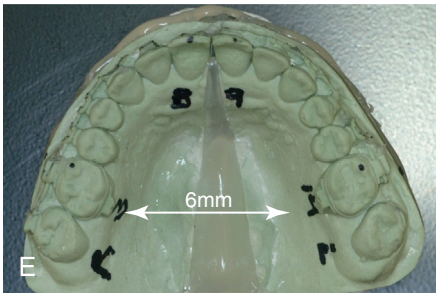
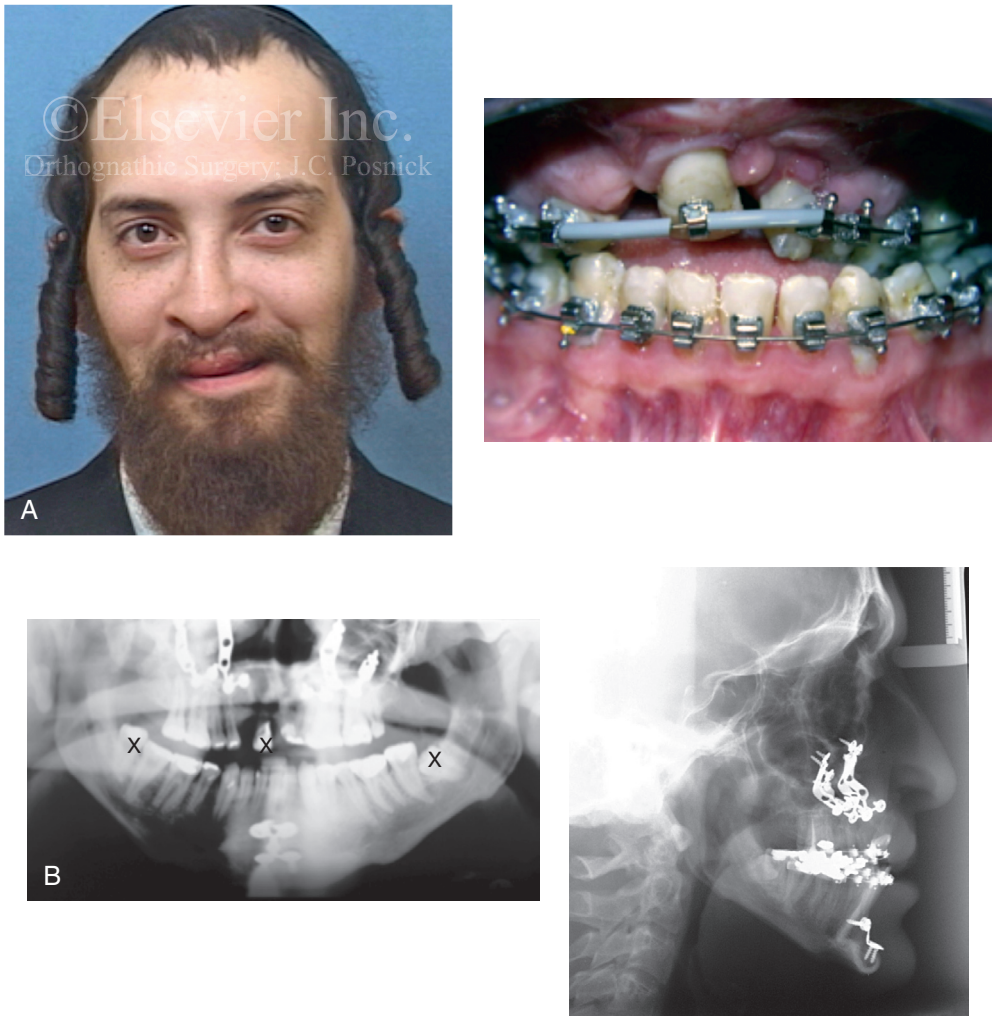
Pre surgery



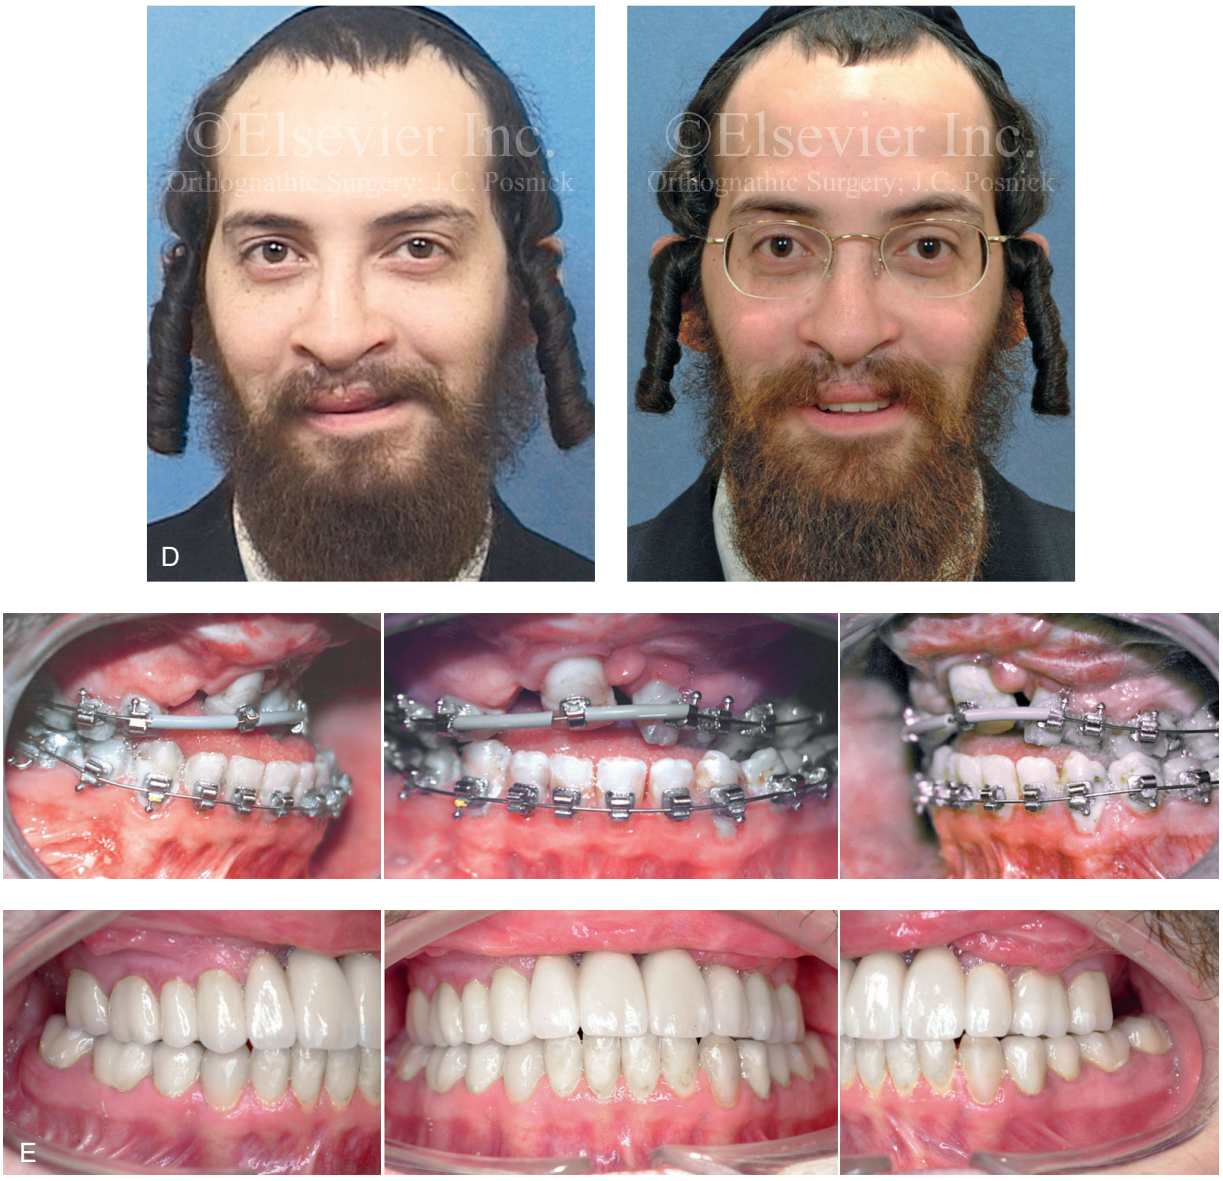




• **Figure 17-3, cont'd** **C,** Occlusal views before retreatment and preoperatively with orthodontic appliances in place. **D,** Articulated dental casts that indicate surgical planning. **E,** Demonstration of the use of the maxillary surgical model to construct a transpalatal arch wire for immediate placement at the time of splint removal (i.e., 5 weeks after surgery). The roof of the patient's mouth is shown with the transpalatal wire in place in accordance with the surgical model. The use of orthodontic mechanics for 6 months to actively maintain the arch width achieved at operation is useful to limit a tendency toward relapse. It is also important to limit any orthodontic mechanics that may position the teeth outside of the alveolar housing, because this situation will be prone to long-term dental relapse.



• **Figure 17-4** A 21-year-old man who was born with bilateral cleft lip and palate arrived for surgical evaluation. He had undergone suboptimal orthognathic surgery (Le Fort I osteotomy and osseous genioplasty) at another institution 4 years earlier. The history, physical examination, and radiographs suggested a combination of both unfavorable initial surgical healing and late dental relapse. The patient was referred to this surgeon and underwent a comprehensive surgical and dental rehabilitative approach. After periodontal evaluation and treatment, orthodontic decompensation was undertaken. The patient's surgery included maxillary Le Fort I osteotomy in three segments with differential repositioning (cant correction, closing down of cleft dental gap, closure of fistula, horizontal advancement, counterclockwise rotation, and vertical adjustment); bilateral sagittal split ramus osteotomies (asymmetry correction); and septoplasty and inferior turbinate reduction. This was followed by planned prosthetic rehabilitation of the maxillary and mandibular arches and ongoing periodontal surveillance. **A,** Frontal and occlusal views at the time of surgical evaluation (i.e., 4 years after the suboptimal orthognathic procedures at another institution). **B,** Cephalometric and Panorex radiographs at the time of surgical evaluation. **C,** Articulated dental casts that indicate analytic model planning.



• **Figure 17-4, cont'd** **D,** Frontal views with smile before and after retreatment including dental rehabilitation. **E,** Occlusal views before and after retreatment including dental rehabilitation.

- Adequate bone contact between the proximal and distal segments, without compression or torquing
- Appropriate alignment of the proximal and distal segments to limit the rotation or torquing of each proximal segment.

4. With the release of IMF, the mandible is put through the range of motion to confirm the adequate stability of the skeletal fixation across the ramus osteotomy site on each side.
5. The occlusion is then checked for any centric relation–centric occlusion discrepancies or other causes of malocclusion. If a discrepancy is seen, each proximal segment must be released of its fixation and then again repositioned until the planned, stable, and reproducible occlusion is achieved (i.e., Steps 1 through 5 are repeated, as needed).

Late Malocclusion after Sagittal Split Ramus Osteotomies

Malocclusion after the successful initial healing of sagittal split ramus osteotomies is the result of either skeletal or dental causes.* *Skeletal causes* may include condylar resorption (see Chapter 36); remodeling or malunion (i.e., relapse) at the osteotomy site; or continued mandibular growth; these conditions are all described in more detail later in this chapter. *Dental causes* of malocclusion after sagittal split ramus osteotomies are often not appreciated

*References 14, 16, 18, 20, 45, 54, 69, 76, 85, 89, 97, 101, 104, 105, 110, 120, 152, 154, 158, 164, 169, 170, 174, 192, 196, 197, 203, 204, 207, 210, 213, 216, 227-229, 232, 252, 256, 272, 273, 285, 297, 308, 312, 316, 326, 328, 334

until much later, but they are generally related to the unstable orthodontic positioning of the teeth outside of the boundaries of the alveolar process before or after surgery; this is discussed later in this chapter (see also Chapters 5 and 6).[208]

Condylar Resorption after Orthognathic Surgery

Although it is rare, *idiopathic condylar resorption* may present after orthognathic surgery (maxillary or mandibular osteotomies), routine orthodontic treatment, or routine dental procedures; it may also occur spontaneously and not in association with any specific form of treatment (see Chapter 36).[12,117,118,143,144,148,159,202,212,237,278,327] *Condylar resorption* is usually bilateral, symmetric, and seen in young females who are between 15 and 35 years old. Although no agreed upon etiology has been delineated for idiopathic condylar resorption, hormonal and autoimmune causes are suspected (see Chapter 36). *Unilateral condylar resorption* in association with compressive forces may also be seen after the excessive use of elastics in an attempt to overcome residual malocclusion. The clinical setting may involve heavy elastic use either as part of an orthodontic camouflage approach to avoid surgery (Fig. 17-5) or after orthognathic procedures that did not achieve the desired occlusion. In either case, heavy compressive forces on the condyle may result in temporomandibular joint symptoms followed by condylar resorption with a loss of condylar (posterior facial) height.

Continued Growth of the Mandible after Orthognathic Surgery

Under normal conditions, the mandible is the last bone in the craniofacial skeleton to complete growth. In general, mandibular growth should be complete between the ages of 14 and 16 years in girls and between the ages of 16 and 18 years in boys. Chronologic and skeletal age will vary from individual to individual, and mandibular growth in men may continue beyond the age of 18 years, but this is uncommon. Jaw growth in girls is usually complete within 2 years after the onset of regular menses. The completion of jaw growth may be assessed in the following ways: 1) via the growth-plate analysis of a hand and wrist radiograph 2) via the analysis of a quantitative condylar head bone scan in comparison to a lumbar vertebra (L2) 3) via the analysis of the mandibular length with the use of serial lateral cephalometric radiographs 4) via the analysis of cervical vertebral maturation with the use of serial lateral cephalometric radiographs 5) via the assessment of serial dental models in centric relation or 6) via the assessment of serial occlusal photographs taken in centric relation.*

Mandibular growth in individuals with micrognathia is generally complete at an earlier age than it is among normal "average" mandibular growers. Alternatively, the cessation of lower jaw growth in individuals with true mandibular excess may occur later than it does in average individuals (Figs. 17-6 and 17-7) (see Chapter 20); this is especially true for individuals with asymmetric mandibular excess growth anomalies (see Chapter 22). Alternatively, the individual with a typical Class II long face growth pattern (i.e., vertical maxillary excess combined with mandibular deficiency) can be assumed to have a normal mandibular growth vector without a tendency for late development (see Chapter 21). I believe that, if the long face patient's chronic nasal obstruction problem is simultaneously managed at the time of orthognathic surgery (i.e., septoplasty, inferior turbinate reduction, the widening of a tight nasal aperture, and the lowering of the nasal floor), further pathologic vertical growth is also likely to be arrested (see Chapter 10).

Ramus Remodeling and Malunion after Sagittal Split Ramus Osteotomy

With the use of rigid internal fixation (e.g., bicortical screws or plates and screws), the remodeling and malunion of the ramus osteotomy site is believed to be an uncommon cause of relapse.[109,115,179,206,236,248,302,324] Although infrequent, infection that has led to sequestration (e.g., of the buccal shelf of the proximal segment) and malunion has been reported. In most clinical settings, there is little evidence to support the concept of late relapse at the ramus osteotomy site after satisfactory initial healing has occurred (by approximately 5 weeks). However, limited bone contact or inadequate fixation of the bony segments may cause initial fibrous union followed by malunion and resulting malocclusion. This would be documented as morphologic change in the mandibular angle (i.e., clockwise rotation of the distal segment) in the presence of unchanged condylar morphology (i.e., no ongoing erosion of the condylar head). There would also be measurable change in either the mandibular length (i.e., as measured from the condyle to the pogonion) or the sella–nasion–B-point angle documented during the analysis of the serial cephalometric radiographs after surgery.

Proffit and colleagues do make a case for ramus remodeling with relapse after mandibular set-back when managing a Class III skeletal pattern.[248] These authors believe that, when the orthognathic procedure for the management of a Class III skeletal pattern is a mandibular set-back only versus a two-jaw surgery (i.e., with the primary movement being maxillary advancement in combination with only minor mandibular adjustment), then relapse at the ramus osteotomy site is a common occurrence. In a recent clinical study, Proffit and colleagues confirmed that—despite improvements in surgical fixation techniques (i.e., rigid fixation versus intraosseous wires and IMF)—when mandibular set-back only procedures are carried out for a Class III malocclusion, skeletal instability is often significant. They confirmed better long-term skeletal and occlusal stability when two-jaw surgery is performed for the management of Class III skeletal patterns (i.e., maxillary advancement with limited mandibular set-back).[251]

*References 26-28, 30, 33-38, 46-48, 68, 81, 92, 94, 119, 129, 130, 201, 214, 215, 218-224, 226, 258, 266, 270, 274-276, 280, 281, 286, 289, 290, 302, 332

• **Figure 17-5** A 23-year-old woman was referred for surgical evaluation. During her high school years, she was recognized as having a malocclusion, and she underwent four bicuspid extractions and orthodontic treatment to neutralize the occlusion. During her college years, she experienced a closed lock of her jaw as a result of a dislocated disc within the left temporomandibular joint. After 3 months of conservative management, the patient underwent arthroscopy with lysis of adhesions. With a recurrence of the closed lock attributed to the disc in the left temporomandibular joint, she underwent discectomy and fat graft interposition. A review of the patient's earlier medical records, including dental models and radiographic analyses, confirmed the primary cause of current malocclusion to be a longstanding developmental jaw deformity that was initially treated with orthodontics alone. Dental relapse had occurred, and the patient's temporomandibular disorder was likely the result of unstable intercuspation. The relief of the temporomandibular disorder was achieved through an open-joint procedure but with the additional loss of posterior facial height and mandibular asymmetry. The patient was referred to this surgeon and agreed to a comprehensive orthodontic and orthognathic approach. The patient's procedures included bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation) and osseous genioplasty (horizontal advancement). Facial balance and satisfactory occlusion were achieved and maintained without the return of temporomandibular disorder. **A,** Frontal views in repose before and after retreatment. **B,** Frontal views with smile before and after retreatment.

• **Figure 17-6** An 18-year-old man with malocclusion and a lifelong history of obstructed nasal breathing was referred for the surgical evaluation. The pattern of deformity was maxillary deficiency in combination with relative mandibular excess, which resulted in a severe Class III negative overjet anterior open bite. He had previously undergone growth modification and camouflage orthodontics including lower bicuspid extractions, without success. After a thorough evaluation, he underwent 12 months of orthodontic decompensation followed by jaw and intranasal surgery. The patient's surgery included Le Fort I osteotomy in segments (horizontal advancement, clockwise rotation, transverse widening, and correction of the arch form) with interpositional grafting; sagittal split ramus osteotomy (minimal counterclockwise rotation); osseous genioplasty (bone burring and recontouring); and septoplasty and inferior turbinate reduction. These procedures were followed by finishing orthodontics. The occlusion achieved during the operation and maintained at the patient's debracketing 6 months later was ideal. By 2 years after surgery, however, a symmetric Class III negative overjet malocclusion had recurred. **A,** Frontal views before and 2 years after reconstruction. **B,** Frontal views with smile before and 2 years after reconstruction.

• **Figure 17-6, cont'd** A review of the 2-year postoperative dental models indicated stable maintenance of the arch width and of the correction of the curve of Spee. The models could be articulated into a similar occlusion as had been achieved at the time of operation. Therefore, the cause of change in occlusion could not be attributed to the segmental osteotomies or dental relapse. The cause of the recurrent malocclusion was felt to be either ongoing mandibular growth or Le Fort I osteotomy site relapse. An analysis of the postoperative cephalometric radiographs—which showed an increase in the sella–nasion–B-point angle and the maintenance of the sella–nasion–A-point angle—confirmed maxillary stability. Ongoing mandibular growth was the cause of the malocclusion. Treatment options included Le Fort I osteotomy (3-mm advancement) versus sagittal split ramus osteotomies (3-mm set-back). The patient was pleased with the functional improvements (i.e., swallowing, speech, chewing, lip closure/posture, and breathing) and the enhanced facial aesthetics without temporomandibular disorders. He elected to receive no further treatment. **C,** Oblique facial views before and 2 years after reconstruction. **D,** Profile views before and 2 years after reconstruction.

Le Fort I Osteotomy: Skeletal Stability and Relapse

Immediate (Early) Malocclusion after Le Fort I Osteotomy

Immediate (early) malocclusion that is recognized either intraoperatively or during the first several days or weeks after surgery may occur after a Le Fort I osteotomy unless the following intraoperative conditions are met (see Figs. 17-1 through Fig 17-4)*:

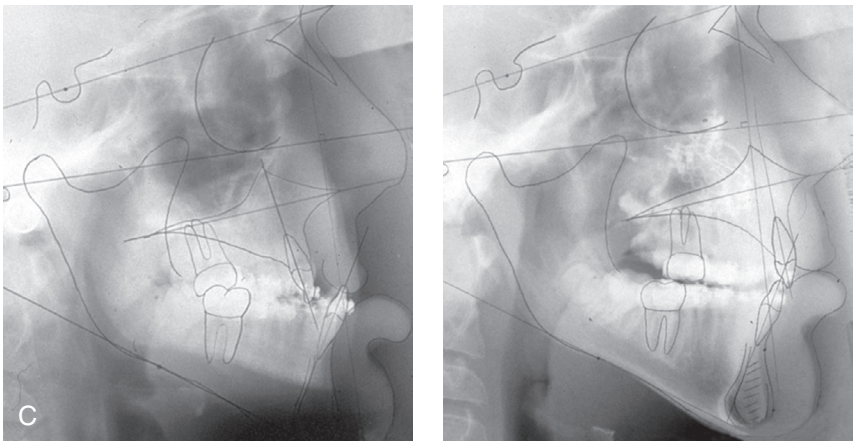
1. After Le Fort I down-fracture osteotomy, full mobilization of the maxilla and the segments (if segmentation has been carried out) is accomplished before the placement of fixation.
2. An accurate prefabricated acrylic splint is secured to the maxillary occlusal surfaces. The splint stabilizes the new maxillary arch form (i.e., the arch width and the curve of Spee) when segmental osteotomies are carried out.
3. After the securing of the splint to the maxillary dentition, IMF is applied to establish the new horizontal position of the maxilla; the dental midline (yaw orientation); the preferred maxillary plane orientation (pitch orientation); and any cant correction (roll orientation) required.
4. With the condyles seated in the terminal hinge position and IMF established via the prefabricated splint, the maxillomandibular complex is rotated until the desired vertical position of the maxilla is achieved.
   - Bony prematurities are common with maxillary impaction. It is easy for the surgeon to overlook interferences in the posterior region of the lateral nasal walls just medial to the descending palatine vessels (see Fig. 15-25, *A* and *B*).

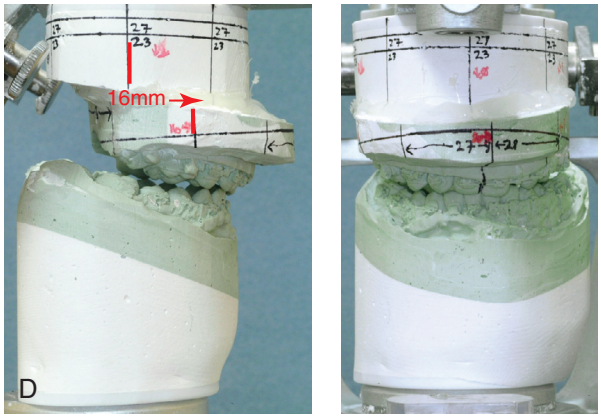
*References 22, 26, 52, 53, 79, 82, 87, 128, 134, 145, 147, 178, 187-189, 191, 193, 194, 233, 234, 239, 241, 244, 259, 264, 279, 287, 307, 317

- Care should be taken to prevent premature contacts across the Le Fort I osteotomy site, which are followed by a "slide" into maximum bone contact during further vertical closure of the maxillomandibular complex. This would cause condylar displacement with malocclusion that should be recognized at the release of the IMF. The malocclusion would typically present as either a symmetric anterior open bite (if both condyles are displaced) or as an asymmetric lateral shift in the bite (if one condyle is displaced).

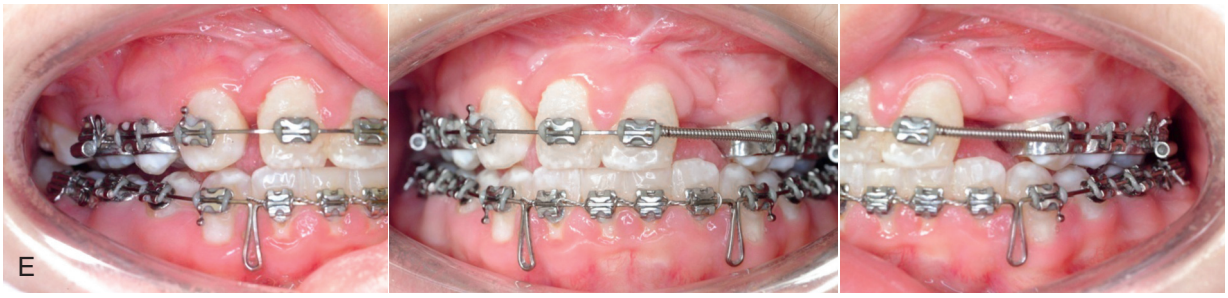
5. There must be adequate bone contact across the osteotomy site after the maxilla is stabilized with plate and screw fixation into the desired position. If not, an interpositional graft of sufficient quality should be placed and secured (see Chapters 15 and 18). Without

• **Figure 17-7** A 13-year-old boy born with bilateral cleft lip and palate arrived for surgical evaluation with a severe cleft jaw deformity. He underwent primary lip and palate repair, a pharyngeal flap procedure, bone grafting, and a columella lengthening procedure at another institution. He was referred to this surgeon with severe maxillary hypoplasia that was causing profound effects on his speech articulation, chewing ability, breathing, and self-esteem. For this reason, early jaw reconstruction was chosen. He underwent maxillary Le Fort I osteotomy (horizontal advancement and vertical lengthening with interpositional [iliac] bone grafting). This was carried out with the understanding that further maxillary growth should not be expected, whereas mandibular growth would likely continue and result in a recurrent Class III. A review of the longitudinal cephalometric radiographs after surgery confirmed no significant horizontal maxillary relapse but ongoing mandibular growth. **A,** Frontal views with smile before and 1 year after surgery just before the removal of the orthodontic appliances. **B,** Oblique facial views before and 1 year after surgery.





Pre surgery



1 year after treatment

• **Figure 17-7, cont'd** **C,** Lateral cephalometric views before and 1 year after surgery. **D,** Articulated dental casts that indicate analytic model planning. **E,** Occlusal views before and 1 year after surgery, just before debanding.

Continued

• **Figure 17-7, cont'd F,** Facial and occlusal views from when the patient was 18 years old (i.e., 5 years after Le Fort I advancement) that indicate recurrent Class III malocclusion as a result of ongoing mandibular growth.

adequate bone contact across the osteotomy site, *fibrous union* may occur (see Chapter 16). Another possibility is that of initial bony union with *relapse* (i.e., *malunion*) occurring as full healing proceeds during the 6 to 12 months after surgery, thereby resulting in late malocclusion.

6. Adequate plate and screw stabilization of the maxilla generally requires the placement of titanium fixation at each pyriform rim and each zygomatic buttress (see Fig. 15-26). When interpositional grafts are required, additional titanium fixation is placed from the superior maxilla and extended across the graft to the dentate segment (see Fig. 15-29, *A, B,* and *C*). Additional plate and screw fixation may also be placed horizontally across any interdental osteotomies, if needed.
7. With release of the IMF, the occlusion is checked as the mandible is rotated (opened and closed) with the condyles seated in the terminal hinge position. The occlusion must evenly contact and fit passively into the splint. If not, the plate and screw fixation across the Le Fort I osteotomy is released. Any bony interference is then identified and removed. The maxilla is again repositioned and the fixation reapplied (i.e., repeat Steps 4 through 7) until the planned occlusion is achieved and confirmed.

Late Malocclusion after Le Fort I Osteotomy

Skeletal causes of a late malocclusion after Le Fort I osteotomy may include the following: 1) remodeling (relapse) at the Le Fort I osteotomy site (as described later in this chapter) 2) fibrous union at the Le Fort I osteotomy site (as described later in this chapter) 3) remodeling (relapse) at the segmental osteotomy sites (as described later in this chapter) 4) condylar resorption (as described previously in this chapter and in Chapter 36)[143] and 5) continued mandibular growth (as described previously in this chapter; see Figs. 17-6 and 17-7).* *Dental causes* of malocclusion after Le Fort I osteotomy are often not realized until much later. They are related to the unstable orthodontic positioning of the teeth outside of the boundaries of the alveolar process before or after surgery (as described later in this chapter and in Chapters 5 and 6).[208]

The precise cause of relapse at the Le Fort I osteotomy site is often difficult to pinpoint , but it is generally related to the following: 1) inadequate mobilization of the down-fractured maxilla before the placement of fixation 2) inadequate bone contact across the osteotomy site after the fixation is applied 3) inadequate (non-rigid) plate and screw fixation across the osteotomy site or 4) excessive occlusal forces or movement transmitted across the osteotomy site during initial healing.†

Fibrous union of the maxilla after Le Fort I osteotomy is an infrequent occurence. When it occurs, expect to find painless mobility of the upper jaw, with or without malocclusion. Risk factors should be recognized, at which point surgical techniques and postoperative management can be adjusted to limit this complication (see Fig. 16-21). The combination of extensive horizontal advancement and vertical lengthening will result in large osteotomy site defects

*References 27, 28, 30, 33-38, 46-48, 68, 81, 92, 94, 119, 129, 130, 201, 214, 215, 218-224, 226, 258, 266, 270, 274-276, 280, 281, 286, 289, 301, 302

†References 3, 4, 11, 14-16, 18-20, 24, 29, 63, 83, 95, 99, 109, 114, 121, 135, 138, 139, 141, 142, 146, 149, 172, 179, 240, 242, 243, 245, 249, 250, 253, 273, 321, 331, 333, 334

with limited bone contact. Failure to form adequate bony bridges at the healing sites is likely to result in delayed healing, fibrous union, or late relapse. Negative influences on bone healing at the Le Fort I osteotomy site may include the following: (1) injury to flap circulation (2) thin osteoporotic bone at the zygomatic buttress and the pyriform rims, with inadequate fixation and (3) the decision to not place interpositional grafts when the bone gaps are of critical size. Additional postoperative healing risk factors include the following: (1) infection or wound dehiscence after surgery (2) the presence of a heavy occlusion (e.g., grinding, clenching) (3) too rapid of a return to normal chewing forces (4) excessive mouth opening against intermaxillary elastics and (5) the breakage (stress fracture) of the fixation plates. Systemic conditions that are known risk factors for poor bone healing include the following: (1) diabetes (2) collagen disease (3) vascular disease (4) osteoporosis or bisphosphonate use (5) nicotine abuse (6) poor nutritional status; and (7) previous radiation treatment.

Relapse across the segmental maxillary osteotomy sites after palatal widening is generally related to the following: (1) inadequate mobilization of the segments (2) inadequate surgical splinting of the new arch shape during initial healing (i.e., the first 5 weeks) (3) inadequate or unstable interdigitating occlusion between the maxillary and mandibular teeth after the splint is removed or (4) inadequate medium-term orthodontic maintenance (i.e., lasting approximately 6 months) with an appropriate appliance after the surgical splint is removed (see Figs. 17-3 and 17-8). Transverse relapse after the removal of the surgical splint may also occur as a result of the use of counterproductive intermaxillary elastic forces. For example, the use of vertical elastics placed on the buccal brackets of the upper and lower molars in an attempt to close posterior open bites may result in the simultaneous unintended collapse of the arch width.

Frequent technical errors that can occur when completing Le Fort I segmental arch expansion and that may result in malocclusion include the following:

1. *Inadequate skeletal mobilization.* When significant widening of the posterior maxilla is required, bilateral (rather than unilateral) parasagittal osteotomies will assist with the tension-free placement of the segments into the splint (see Chapter 15).
2. *Inadequate splint strength.* The use of a non-flexible splint (e.g., a reinforced U-shaped acrylic splint, transpalatal support) is essential to maintain the arch width during initial healing (see Chapter 13).
3. *Inadequate soft-tissue mobilization.* After the completion of segmental osteotomies, the stretching of the palatal soft tissues through the down-fracture (i.e., the use of a spreader forceps) improves the tension-free placement of the segments into the splint.
4. *Inadequate postsurgical care.* After the splint is removed (i.e., 5 weeks after surgery), the seamless transfer of responsibility from the surgeon to the orthodontist for ongoing maxillary arch form maintenance is essential. The effective use of orthodontic mechanics is generally needed for at least 6 months to retain the arch form. (This is described later in this chapter.)

Orthodontic Treatment: Dental Stability and Relapse

The objective of orthodontics in conjunction with jaw surgery is to align the dentition in each arch by placing the maxillary and mandibular teeth fully within the basal bone. When the jaws and jaw segments are then surgically repositioned, the preferred occlusion is achieved. Following Andrews' Six Keys to Normal Occlusion provides the framework for the accomplishment of the orthodontic objectives (see Chapters 5 and 6).[208]

Moen and colleagues carried out a prospective clinical study to evaluate the short-term occlusion achieved and the long-term occlusion maintained after bilateral sagittal split ramus osteotomies with advancement for the treatment of Class II skeletal deformities.[208] Prospectively, 36 patients with Class II skeletal patterns who were to undergo bilateral sagittal split ramus osteotomies agreed to participate in the study. The mean age at operation was 33 years (range, 16 to 59 years). All of the study patients underwent perioperative orthodontics and were followed clinically, with dental models and radiographs (i.e., lateral cephalometric and Panorex). These standard records were obtained at 8 weeks, 1 year, and 13 years after surgery. Interestingly, for the majority of patients, cephalometric analysis confirmed insignificant skeletal changes during long-term follow up after successful initial healing had occurred. Long-term recurrent malocclusion was found to be primarily dental rather than skeletal in origin.[208] *To achieve and then maintain the ideal occlusion, the importance of the stable orthodontic positioning of the teeth in the alveolus cannot be overstated* (Figs. 17-9 through 17-14).

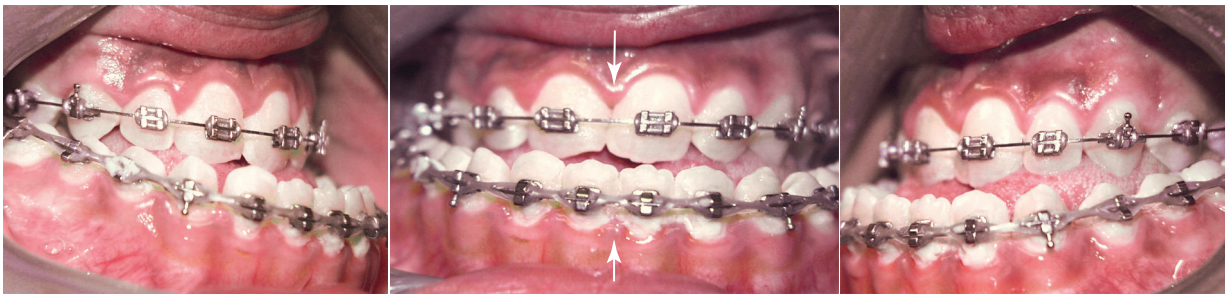
The lips, tongue, cheeks, soft palate, mandible and periodontal ligaments function dynamically with the stationary (immobile) maxilla and the teeth to achieve chewing, swallowing, breathing, speech, and lip closure. Parafunctional habits of these structures (e.g., posturing of the tongue, lips, and jaw) may influence the position of the teeth and the supporting skeletal structures. *Dental compensations* are expected biologic responses when a jaw disharmony is present at birth or when it occurs during growth. The orthodontic mechanical removal of dental compensations should position the teeth within the alveolar process to then maximize the surgical correction and also to provide a framework for long-term occlusal stability and periodontal health.*

Extraction Therapy to Eliminate Crowding

Dental extractions may be necessary when there is inadequate alveolar bone to eliminate the dental crowding and

*References 2, 7, 55, 61, 71, 77, 78, 80, 93, 100, 103, 157, 186, 190, 205, 217, 247, 246, 267, 288, 330, 335, 336

• **Figure 17-8** A 15-year-old high school student was referred by her orthodontist for surgical evaluation of a long-standing developmental jaw deformity with malocclusion and a lifelong history of obstructed nasal breathing. The pattern of growth disturbance was maxillary deficiency in combination with relative mandibular excess, and this resulted in a Class III negative overjet anterior open bite malocclusion. The patient had undergone growth modification and camouflage orthodontics, without success. Referral to this surgeon was followed by orthodontic decompensation in conjunction with jaw and intranasal surgery and then finishing orthodontics. The patient's surgery included maxillary Le Fort I osteotomy in two segments (horizontal advancement, transverse widening, and vertical lengthening); sagittal split ramus osteotomies (counterclockwise rotation and minimal horizontal advancement); and septoplasty and inferior turbinate reduction. The surgical occlusion that was initially achieved at operation and then maintained during the early phase of healing was stable. By 6 to 12 months after surgery, a degree of posterior crossbite had recurred. **A,** Frontal views with smile before and after reconstruction. **B,** Oblique facial views before and after reconstruction.



Pre surgery

2 years after treatment

• **Figure 17-8, cont'd** A review of the postoperative dental models indicated intermolar transverse constriction as compared with what was surgically planned, executed, and achieved at 5 weeks after surgery, when the prefabricated splint was removed. A review of the dental models confirmed a combination of skeletal and dental relapse that resulted in maxillary arch constriction. In retrospect, the postoperative orthodontic mechanics of the labial arch wire to maintain the surgically achieved arch width were not adequate. The use of a transpalatal wire or an acrylic palatal plate maintained for 6 months after surgery may have prevented maxillary arch form relapse after the surgical splint was removed (i.e., 5 weeks after surgery). Treatment options for the residual malocclusion include redo Le Fort I segmental osteotomies with expansion versus surgically assisted rapid palatal expansion. The patient was pleased with the improvements (i.e., chewing, speech articulation, lip closure/posture, and breathing) and the enhanced facial aesthetics. She was left with a functional occlusion without centric relation–centric occlusion discrepancies or temporomandibular disorder. She elected to receive no further treatment. **C,** Profile views before and after reconstruction. **D,** Occlusal views with orthodontic decompensation in progress and 3 years after treatment. The positive overjet overbite is maintained but with recurrent maxillary transverse constriction.

to remove compensations without displacing the roots outside of alveolar housing. Opinions regarding the indications for extractions have changed remarkably over the past 150 years since the beginning of "modern" orthodontics.

During the 1880s, Edward Angle joined other progressive restorative dentists of his time in their opposition to a casual attitude toward the extraction of teeth (see Chapter 2). Angle's belief was that, through diligent effort, the orthodontic alignment of the full complement of teeth was possible. He felt that the orthodontist's ultimate objective was for every person to have the potential for an ideal relationship of all 32 natural teeth.

Dr. Angle believed that the cause of most Class II or Class III problems was often the result of abnormal stresses on the jaws. Through the orthodontist's active application of controlled pressure on the teeth (i.e., arch expansion) and occasionally directly on the bone (i.e., chin cup and headgear), Dr. Angle believed (at least early during his career) that the clinician could change jaw growth and overcome the presenting Class II or Class III deformity.

Angle also taught that proper jaw and dental function on the part of the individual should maintain the teeth in their orthodontically corrected position. He believed—or at least hoped—that, after the teeth were placed in proper occlusion, the natural forces transmitted to the teeth would cause alveolar bone to generate around them.

Through trial and error, he realized that simply tipping the teeth into a new position was often inadequate. He developed the *Ribbon Arch* appliance and then the *Edgewise* appliance to "bodily" move the teeth. These were the first clearly described and reliably designed orthodontic appliances that were capable of controlling root position. At this time, Dr. Angle claimed that these were "bone-growing appliances."[10] For Angle, this work was simply an extension of Wolff's law of bone, which states that the internal architecture of a bone represents the stress pattern that is placed on it.

Angle's treatment philosophy involved arch expansion with the use of vectored rubber bands and other appliances, as needed, to bring the teeth into occlusion. To Angle, at least early during his career, the term *relapse* as it applied after orthodontic expansion that had been carried out to uncrowd and correct overjet or overbite simply meant that the achieved occlusion was inadequate or technically incorrect. According to Angle, "If a correct occlusion had been produced [by the orthodontist] the result would be stable."[10] Therefore, he felt, "if the orthodontic result was not stable, the fault was either that of the orthodontist or poor compliance by the treated patient, not the theory."[10]

For the most part, Angle believed that, for each individual, ideal facial aesthetics would result when the teeth were placed in ideal occlusion. Whether the patient agreed or not, by divine definition, the best facial appearance for that patient would be achieved when the dental arches had been expanded so that all of the teeth were in ideal occlusion. Angle adamantly believed that extractions were not indicated.

Text continued on p. 592

• **Figure 17-9** A female high-school student was referred by her orthodontist for surgical evaluation. Since her mid childhood years, the patient was known to have a long face growth pattern, and she had a lifelong history of obstructed nasal breathing. She had undergone attempted growth modification followed by orthodontic camouflage, without success. At the time of referral, the patient's concerns included lip incompetence, gummy smile, weak profile, malocclusion, and nasal obstruction. She agreed to a surgical correction. The orthodontic treatment plan then changed in preparation for orthognathic surgery. Extractions were not carried out to correct the maxillary and mandibular arch forms. The patient then underwent maxillary Le Fort I osteotomy (horizontal advancement and vertical intrusion); bilateral sagittal split ramus osteotomies (minimal horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical reduction and horizontal advancement); and septoplasty, inferior turbinate reduction, and recontouring of the nasal floor. Successful initial surgical healing was achieved. The occlusion maintained at splint removal (i.e., 5 weeks after surgery) was as planned. The orthodontic appliances were removed 6 months after surgery, with ideal occlusion and orthodontic retention continued. The patient returned 3 years after surgery with complaints of recurrent anterior open-bite malocclusion. **A,** Frontal views in repose before and 3 years after surgery. **B,** Frontal views with smile before and 3 years after surgery.

• **Figure 17-9, cont'd** An analysis was carried out that included the review of lateral cephalometric and Panorex radiographs taken before surgery, 5 weeks after surgery, and 3 years after surgery. The patient had no temporomandibular disorder, and there was no evidence of condylar resorption. Therefore, idiopathic condylar resorption was ruled out. Cephalometric analysis of the presurgical, early postoperative, and late postoperative cephalometric radiographs revealed satisfactory initial repositioning and healing of the jaws without skeletal relapse at 3 years. A comparison of the 5-week postoperative and 3-year postoperative sella–nasion–A-point and sella–nasion–B-point angles and facial heights confirmed skeletal stability. A review of the arch form (i.e., the dental models) suggested orthodontic relapse that included transverse maxillary constriction and incisor intrusion. The mandibular arch form also indicated dental relapse. Treatment options included redo Le Fort I osteotomy in three segments for the correction of the arch form versus surgically assisted rapid palatal expansion. Orthodontics would also be required. The advantages of four bicuspid extractions as part of dental decompensation were also discussed. The patient was pleased with the enhanced facial aesthetics (i.e., a less gummy smile, an improved profile, and lip closure) and the improved breathing that was achieved. She also did not have any temporomandibular disorder. She elected to receive no further treatment. **C,** Oblique facial views before and 3 years after surgery. **D,** Profile facial views before and 3 years after surgery.

• **Figure 17-10** A 14-year-old girl was referred by her orthodontist for surgical evaluation. She presented with a long face Class II growth pattern and a lifelong history of obstructed nasal breathing. She underwent non-extraction orthodontics, including mechanics to correct the maxillary arch form. The patient's surgery included maxillary Le Fort I osteotomy (vertical intrusion, horizontal advancement, and counterclockwise rotation); sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical reduction and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. Healing occurred without complications. The occlusion that was initially achieved and maintained at 5 weeks after surgery was as planned. Unfortunately, the patient refused continued postoperative orthodontics and the appliances be removed 3 months after surgery. She was also not compliant with retainer use. By 1 year after surgery, there was a recurrence of the anterior open bite. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

Continued

• **Figure 17-10, cont'd** A review of the dental models confirmed dental relapse with a recurrent accentuated curve of Spee and arch constriction of the maxilla. In retrospect, segmental orthodontic mechanics followed by segmental maxillary surgery would likely have prevented this problem. At this time, treatment options include segmental orthodontic mechanics and redo Le Fort I osteotomy in segments. The patient and her family were pleased with the improvements in lip closure/posture, a diminished gummy smile, improved profile aesthetics, and better breathing during the day and night. The patient did not have temporomandibular disorder, and she elected to received no further treatment. **C,** Oblique facial views before and after treatment. **D,** Profile views before and after treatment.

• **Figure 17-11** A 17-year-old boy was referred by his orthodontist for the surgical evaluation of a long-standing developmental jaw deformity with malocclusion and a lifelong history of obstructed nasal breathing. The patient had undergone both growth modification and camouflage orthodontics, without success. Examination confirmed a Class III long face growth pattern with an anterior open bite. He then underwent orthodontic mechanics in preparation for jaw surgery. The maxillary arch was leveled with orthodontic mechanics. The patient's surgery included maxillary Le Fort I osteotomy (horizontal advancement, vertical shortening, and clockwise rotation); bilateral sagittal split osteotomies of the mandible (minimal set-back and clockwise rotation); and septoplasty, inferior turbinate reduction, and nasal base recontouring. An osseous genioplasty with horizontal advancement would have further enhanced the patient's facial aesthetics but was refused. The surgery was followed by finishing orthodontics. The patient's occlusion at 5 weeks after surgery was excellent, and it remained so at the time of the debracketing 6 months after surgery. By 1 year after surgery, a slight Class III tendency with posterior constriction was evident. **A,** Frontal views in repose before and after surgery. **B,** Frontal views with smile before and after surgery.

Continued

• **Figure 17-11, cont'd** By 2 years after surgery, the anterior occlusion was edge to edge, and the maxillary arch form was irregular. The cause of the recurrent malocclusion was felt to be either ongoing mandibular growth or a loss of maxillary arch form as a result of dental relapse. A review of the cephalometric data suggested stability of the mandible (i.e., the sella–nasion–A-point and sella–nasion–B-point angles were unchanged at intervals after surgery). A review of the dental models confirmed dental relapse with a change in the maxillary arch form (i.e., constriction in the arch width and an accentuated curve of Spee). Treatment options include maxillary Le Fort I osteotomy in segments for the correction of the arch form versus surgically assisted rapid palatal expansion. An osseous genioplasty was also offered to improve the patient's profile aesthetics. The patient was pleased with the functional improvements (i.e., chewing and speech articulation), and he did not have temporomandibular disorder; he also appreciated the enhanced facial aesthetics. He elected to receive no further treatment. **C,** Oblique facial views before and after surgery. **D,** Profile views before and after surgery.

• **Figure 17-12** A 20-year-old female college student was referred for surgical evaluation. During the mixed dentition, she was noted to have a long face growth pattern with an anterior open bite. She was treated from the time that she was 11 to 15 years old with growth-modification followed by a four-bicuspid orthodontic camouflage approach, without success. She presented for surgical evaluation with complaints of chronic obstructed nasal breathing; an anterior open bite that caused difficulty with chewing and with speech articulation; wide lip separation with lip strain at closure; and a retrusive profile appearance. There was generalized root resorption and early anterior mandibular labial bone loss and gingival recession. A comprehensive evaluation also confirmed septal deviation and inferior turbinate hypertrophy with increased nasal airway resistance. The patient agreed to an orthodontic and orthognathic/intranasal surgical approach. Her surgery included maxillary Le Fort I osteotomy in segments (arch form correction, horizontal advancement, vertical shortening, and counterclockwise rotation); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

• **Figure 17-12, cont'd** The occlusion that was initially achieved and maintained at 5 weeks after surgery was as planned. Postoperative orthodontic appointments were complicated by the patient's attendance at an out-of-state college. At the time of appliance removal (i.e., 10 months after the operation), there was partial recurrence of the anterior open bite. The occlusion then remained stable at the 18-month postoperative interval. There was no popping, clicking, or pain in either temporomandibular joint. There was mild masticatory muscle discomfort, which was relieved with an effective night guard. An analysis of the postoperative cephalometric radiographs, which were taken at 1 month and 18 months after surgery, confirmed a stable SNB angle. The condyle-to-gonion measurement also remained stable. A review of the condyle morphology on the Panorex radiograph revealed no significant change. A review of the dental models (i.e., the surgical planning models and those from 16 months after surgery) suggested a degree of dental relapse in the form of recurrent curve of Spee issues in the maxilla and the mandible. The patient elected to undergo no further treatment. **C,** Oblique facial views before and after treatment. **D,** Profile views before and after treatment.

Calvin Case, who was a prominent contemporary and outspoken critic of Angle, used contouring appliances and light rubber bands to move the teeth. *He argued that, although the arches could be expanded and the teeth aligned, in the long term, occlusal stability was not always satisfactory, and facial aesthetics could be compromised.*

By around 1915, Case had worked out most of the mechanical principles required for the successful management of orthodontic extraction sites. With the use of full-banded appliances, he was able to routinely retract the anterior teeth into the bicuspid extraction sites to correct the inclination of the anterior teeth and to eliminate crowding. Interestingly, only about 10% of his patients were treated with extractions.

Debate in dental circles regarding the issue of extractions continued between Angle's disciples and Case's followers throughout the 1920s. The Dewey–Case "Great Extraction Debate" took place in 1911. Angle's non-extraction/arch expansion approach continued to predominate with the everyday practitioner until after World War II. Angle's philosophy was widely accepted as a result of his well-written and popular textbook; his abilities as a teacher and lecturer; his consistent treatment philosophy; and his success as a diligent clinician.

By the late 1930s, when non-extraction treatment was used on all comers, relapse was a frequent observation that could no longer be ignored. After Angle's death, his student *Charles Tweed* began re-treating a number of Angle's patients who had experienced relapse. Tweed's retreatment approach included *four bicuspid extractions followed by the realignment of the remaining dentition.* He observed greater occlusal stability with this approach. By the mid-1940s, Tweed's well-documented series of cases involving four premolar extractions with orthodontic retraction caused a revolution in orthodontic thinking that led to widespread extraction therapy in everyday orthodontic practice. Interestingly, *Raymond Begg,* who was another of Angle's students and who was at this time halfway around the world in Australia, also *concluded that non-extraction treatment was frequently unstable.* Like Tweed, Begg modified the Angle-designed Edgewise appliance into what he called the "Begg appliance" for use with extraction therapy.

The acceptance of extraction therapy in orthodontics to stably position the teeth into alveolar housing coincided

with an appreciation that genetic variations—with disparities between tooth root volume and jaw size—are common among normal individuals and will differ among races (see Chapter 3). That a presenting jaw or dental discrepancy could benefit from extractions was simply an admission of a patient's individuality rather than the orthodontist's inability to solve all problems in the same way. *By the early 1960s, approximately 50% of American patients who were undergoing orthodontic treatment would experience the extraction of at least some teeth, most commonly the first premolars*.

Orthodontists have also used extractions as a means to achieve a neutralized occlusion in the presence of a skeletal discrepancy (i.e., a *camouflage approach*). This involves achieving an improved occlusion while accepting the jaw (facial) disharmony. Examples of this approach include upper bicuspid extractions to orthodontically treat mandibular retrognathism or lower bicuspid extractions to orthodontically manage Class III skeletal patterns. Interestingly, this orthodontic camouflage approach became common practice during the 20th century, despite the fact that, by the early 1900s, mandibular surgery had been performed for both Class II and Class III skeletal deformities. *In reality, corrective jaw surgery was rarely considered an option (except by a handful of orthodontists and surgeons) until the later decades of the 20th century* (see Chapter 2).

By the 1990s, overemphasis on four bicuspid extractions as part of routine orthodontic treatment began to wane in favor of a more discriminating approach. The rationale for selective extractions as part of a comprehensive surgical and orthodontic approach has now been confirmed to be effective for the removal of dental compensation. Extraction orthodontic therapy in combination with jaw osteotomies to correct the occlusion, for long-term periodontal health, to improve the upper airway, and to enhance facial aesthetics is now considered routine for many patients. The interproximal reduction of enamel as an alternative to extractions was popularized by Dr. J. Sheridan during the 1990s. In borderline cases, it has been found to provide the necessary space for incisor uprighting (see Chapters 5 and 6).

Research confirms that clinicians and the general public prefer a face with full midface projection and with prominent teeth and lips.[231,257,261] The "flat face" orthodontic standards of Tweed, which were typical during the 1950s and the 1960s, retracted rather than expanded (i.e., filled out) the face. In borderline cases, the patient's facial appearance is generally judged as being better without extractions. The decision to extract should be viewed in the light of attaining Andrews' Six Keys to Normal Occlusion and Six Elements of Orofacial Harmony (see Chapter 2). The primary goals are to achieve: (1) the placement of teeth solidly in the alveolar bone (2) ideal dental alignment within and between the arches and (3) the adequate position and projection of the maxillomandibular complex (i.e. facial harmony). If jaw surgery (with or without extractions) is required to achieve these objectives, it should be incorporated into the treatment plan from the outset for the benefit of the patient.

An alternative to the extraction of teeth for the relief of crowding in the maxilla is to expand the volume of the alveolar ridge. This may be accomplished via one of three techniques: (1) rapid palatal expansion (RPE) with the use of a transpalatal appliance if the palatal suture is open (i.e., 0.5 mm of widening per day); (2) surgically assisted rapid palatal expansion (SARPE) followed by transpalatal appliance widening (i.e., 0.5 mm of widening per day); (3) segmental maxillary osteotomies (i.e., Le Fort I down-fracture and full disimpaction) with immediate repositioning to correct the arch form. These three options are not equally appropriate for each individual patient. The level of success of each of these options will be dependent on the clinical circumstances.

Orthodontic Treatment of Specific Dentofacial Growth Patterns: Dental Stability and Relapse

Primary Mandibular Deficiency Growth Pattern with or without Maxillary Arch Constriction (Skeletal Class II)

Findings

For the patient who presents with mandibular deficiency, dental compensations often include crowding and flaring of the lower incisors with an accentuated curve of Spee. This is a natural biologic response to the eruption of a full complement of teeth within a small mandible. This is exacerbated by constant protrusive tongue activity in combination with limited lip forces within a small oral cavity. These dental compensations are inevitable when the combined size of the mandibular teeth is greater than the available alveolar bone volume within a hypoplastic lower jaw. The anterior teeth (i.e. dental roots) follow the path of least resistance and frequently protrude outside of the labial cortex. In this dysfunctional matrix, the lower incisor inclination—when viewed on a lateral cephalometric radiograph—is obtuse, and it often substantially exceeds the normal range (i.e. 90 to 95 degrees). The extent of incisor protrusion is indicative of the degree of mandibular hypoplasia, and the unequal forces of the tongue and lips. In approximately one third of cases, there is also a degree of maxillary arch-width deficiency that requires correction; this is described in more detail later in this chapter.

Orthodontic Approach in Conjunction with Orthognathic Surgery

In the presence of moderate to severe mandibular deficiency, the ideal positioning of the lower anterior teeth is best accomplished by first carrying out extractions to create space. This most often involves the removal of the lower first bicuspids. When less space is required and the occlusion will accommodate it, the extraction of a single lower incisor is an option to consider. In borderline cases and depending on the specific patient's dental anatomy, interproximal reduction of the anterior teeth may provide sufficient space. The orthodontist's ability to achieve lower incisor inclination of approximately 90 to 95 degrees will be a good indication of the overall relief of dental compensation within the mandibular arch.

The failure to remove these compensations limits the surgeon's ability to position the mandible for ideal facial proportions, and for the relief of airway obstruction (i.e., opening of the retroglossal space). An advancement genioplasty to further enhance aesthetics and lip function is also generally beneficial to manage microgenia (see Chapter 19). If the surgeon "over-advances" the chin as a "skeletal compensation" for the inadequate orthodontic removal of incisor flaring, then further facial disproportion (i.e., a deepening of the labiomental fold with an overly prominent pogonion) is likely to occur (see Chapters 37 and 40).

Another aspect of dental compensation frequently seen in the individual with mandibular deficiency is a deep bite and an accentuated curve of Spee. In this case, first bicuspid extractions are often beneficial. At the time of mandibular advancement with incomplete flattening of the curve of Spee, the occlusion may be placed in a "tripod" relationship. After surgery, the resulting mid-arch open bites are closed by extruding the bicuspids with vertical elastics. These mid-arch open bites are generally more efficiently managed after surgery, when the lower anterior facial height is increased and the mandible has been advanced. After surgery, the expanded intraoral volume no longer creates the same degree of anterior and lateral tongue forces that oppose the orthodontic correction of the curve of Spee and the closure of extraction sites. The reduction in bite force early after surgery also assists with the rapid leveling process.

If interarch-width discrepancies are present—as they are in approximately one third of cases—then simultaneous Le Fort I osteotomy with segmentation (i.e., into two or three segments) is generally carried out to widen and correct the maxillary arch form (see "Management of Transverse Maxillary Deficiency" later in this chapter). When only minimal upper arch width deficiency exists and no other reasons warrant maxillary osteotomy, mandibular narrowing to balance the arches can be considered. This may be accomplished by completing a vertical midline osteotomy between the mandibular central incisors. The use of this option for mandibular narrowing is usually a distant second choice (vs. maxillary expansion) for the resolution of interarch discrepancies. Adding width to the upper jaw is generally preferred for the airway and to enhance smile aesthetics (i.e., for the relief of dark buccal corridors).

Maxillary Deficiency with Relative Mandibular Excess Growth Pattern (Skeletal Class III)

Findings

In a patient with maxillary deficiency and relative mandibular excess, the normal dental compensations generally include maxillary incisor protrusion and upright or retroclined mandibular incisors (see Chapter 20).

Orthodontic Approach in Conjunction with Orthognathic Surgery

With this common dentofacial growth pattern, the extraction of the first bicuspids in the maxillary arch to uncrowd and reposition the incisors (approximately 120 degrees to the Frankfort plane or 102 to 104 degrees to the sella–nasion plane) should be considered. With only borderline crowding and limited incisor flaring the decision for maxillary extractions becomes more difficult. Also, a degree of maxillary incisor flaring may be aesthetically tolerated when planning bi-maxillary osteotomies, which incorporate clockwise rotation of the maxillo-mandibular complex to correct any A-point–B-point facial disharmony (see Chapter 12).

If interarch width discrepancies (posterior crossbites) require correction, then simultaneous segmentation of the down fractured maxilla (2 or 3 segments) is carried out (see "Management of Transverse Maxillary Deficiency" later in this chapter).

In the mandibular arch, the incisors are generally retroclined, and a reverse curve of Spee is often excessive. Mandibular extractions are only indicated if there is significant crowding in the lower arch with inadequate alveolar bone.

In the patient with a skeletal Class III growth pattern, the failure to orthodontically remove these specific dental compensations as part of the comprehensive orthodontic and surgical approach is likely to negatively affect long-term occlusal stability, periodontal health, and the achievement of preferred Euclidian facial proportions.

Long Face Growth Pattern: Maxillary Vertical Excess with Mandibular Deformity

Findings

A long face growth pattern classically includes maxillary deformity (vertical excess, transverse deficiency, and a lack of horizontal projection), mandibular deformity (high-angle retrognathia), and deformity of the chin (vertical excess and sagittal deficiency). Of note is that the mandibular deformity may also present as a Class III rather than the more common Class II growth pattern (see Chapters 4 and 21).

The biologic dental compensations in the maxillary arch are reflective of the skeletal transverse deficiency and the differential degrees of maxillary vertical alveolar excess (i.e., the anterior and posterior aspects of the maxilla). If there is marked dental crowding in the maxilla, then bicuspid extractions will be indicated. In the lower arch, depending on the extent of mandibular micrognathia and flaring of the incisors, limited space for the orthodontic retraction of the teeth may be present. If so, mandibular first bicuspid extractions will generally be indicated followed by orthodontic retraction and alignment.

Orthodontic Approach in Conjunction with Orthognathic Surgery

The preoperative orthodontic leveling of a moderate to severe curve of Spee in the maxilla is ideally performed with segmental arch mechanics. This is necessary to match the dental alignment with the extent of dysmorphic anterior and posterior alveolar bone. This is done in preparation for segmental maxillary osteotomies, which will then level the curve of Spee and adjust the arch width. This segmental orthodontic preparation places the teeth solidly in the available alveolar bone within each component (segment) of the

upper jaw. This avoids the extrusion of the anterior teeth and the buccal tipping of the posterior dentition. Given the usual degree of dysmorphic maxillary alveolar bone, attempts to level the dentition solely through orthodontic mechanics (i.e., via incisor extrusion and molar intrusion) are periodontally unsound; they may result in incisor root resorption, and they are prone to late dental relapse with recurrent malocclusion (see Fig. 17-9).

Surgical segmentation of the maxilla between the lateral incisors and the cuspids and then parasagittally through the hard palate is generally performed to achieve the desired arch width, the leveling of the curve of Spee, and the adjustment of incisor inclination. The canine and lateral incisor roots are naturally divergent, so there is no need (or advantage) for the orthodontist to create a space to "make the segmental surgery safe" (see Chapter 15). There is little risk of causing intraoperative injury within the periodontal ligament space or to the tooth roots or of creating periodontal pocketing when completing the interdental osteotomies in these locations.

To review, the orthodontic correction of the maxillary arch form with vertical mechanics (i.e., the extrusion of the incisors and molar intrusion) and dental expansion (i.e., molar tipping) in a patient with a long face anterior open-bite malocclusion is unstable. It is likely to be injurious to the periodontium, with labial bone loss and gingival recession in the molar region, and it is more likely to result in the blunting of the incisor root apices. In addition, attempting closure of the anterior open bite via the orthodontic extrusion of the incisors would accentuate the gummy smile, further flatten the appearance of the face in profile, and not address the lip incompetence.

Management of Transverse Maxillary Deficiency: Techniques and Relapse Patterns

Background

The orthodontic management of isolated transverse maxillary deficiency in children and adolescents with an open palatal suture by *rapid palatal expansion* (RPE) and conventional orthodontic techniques is generally possible, although stability can be troublesome.* In the non-growing individual, if standard orthodontic techniques are used for expansion beyond a few millimeters, they will produce either buccal tipping of the maxillary molars or lingual tipping of the mandibular molars with an unstable long-term occlusion and the potential for injury to the periodontium. The molars will likely relapse palatally, thereby causing clockwise rotation of the mandible with recurrent anterior open bite.

The literature confirms that a transverse maxillary deficiency that presents after palatal suture closure (i.e., an age of >14 years) should be managed surgically.* This can be done with either "surgical assistance" followed by rapid expansion using an in-place palatal appliance (the process known as *surgically assisted rapid palatal expansion* [SARPE]) and then orthodontic realignment or by *segmental Le Fort I maxillary osteotomies* in conjunction with standard orthodontics. The latter approach is carried out when clinically indicated as a one-stage procedure in combination with vertical, horizontal, and other needed surgical repositioning of the maxilla (these two approaches are discussed in more detail later in this chapter). The magnitude of segmental maxillary expansion that a surgeon is comfortable achieving is dependent on that clinician's experience and the unique aspects of the specific patient's palatal anatomy.

Proffit and colleagues reported that individuals who are seeking evaluation for orthognathic surgery have a 30% incidence of transverse jaw discrepancies.[252] True (absolute) transverse discrepancy exists when one or both of the posterior maxillary segments are in a crossbite when the casts are placed into a normal overjet and overbite position after the relief of dental compensation. This will tend to unmask arch-width discrepancies in patients with Class II malocclusions and correct a percentage of those in patients with Class III malocclusions. True transverse arch discrepancies are frequently seen in patients with 1) Class II retrognathic mandibles 2) long face Class II anterior open bites 3) those with previous thumb-sucking habits resulting in anterior open bite and 4) patients with cleft palates and maxillary deficiency.

Vanarsdall and colleagues have defined transverse skeletal discrepancies through measurements that are made on posteroanterior cephalometric radiographs.[314] The authors measured maxillary (skeletal) width from the *jugular point* on one side to the jugular point on the other side. They compared this measurement to the skeletal lower arch width measured from the *antegonial notch* on one side to the antegonial notch on the other side. From these two measurements, the determination of a *differential index* can be made. These researchers suggested that a preferred differential index should be approximately 20 mm in the adult Caucasian individual. Preadolescent patients will normally have a lower differential index. The authors believe that an adult with a differential of 30 mm has a significant transverse problem. According to Vanarsdall and colleagues, a differential index that varies by more than 5 mm from these values requires correction in the maxilla to establish a long-term stable occlusion and satisfactory periodontal health.[314] With the advent of three-dimensional cone beam computed tomography imaging, the more accurate measurement of the transverse maxillary width is likely available. Further research is required to confirm normal values for maxillary and mandibular arch width.

Gingival recession in any given individual is likely to have multifactorial causes. Tooth position within the alveolar

*References 13, 21, 25, 31, 32, 42, 56, 59, 60, 62, 64-66, 167, 171, 176, 225, 235, 238, 252, 260, 284, 299, 303, 314

process is an important factor, especially in the patient who is biologically susceptible to recession (i.e., with limited attached gingiva; see Chapters 5 and 6). According to Vanarsdall and colleagues, the most common risk factors for the gingival recession of the maxillary posterior dentition include 1) friable attached gingiva 2) genetic factors 3) emotional stress 4) inadequate labial bone and 5) buccally tipped maxillary posterior teeth (i.e., dental compensation).[314] These factors will cause the periodontium to "receive" rather than "transmit" forces, with likely continued bone loss and gingival recession occurring over time.

Vanarsdall and colleagues suggest that periodontal susceptibility to breakdown has a relationship to the position of the teeth within the arch and to the relationship of the opposing teeth when they are in occlusion (see Chapters 5 and 6).[314] The initial experimental work of these researchers shows a decrease in the numbers of pathogenic bacteria around the teeth after the teeth have been aligned into a more natural position (i.e., to more closely agree with Andrews' Six Keys to Normal Occlusion). With good dental alignment, the numbers of harmful bacteria were brought below the threshold at which damage to the periodontal tissues frequently occurs. It is also believed by many clinicians that the achievement of maxillomandibular occlusal harmony (i.e., the correction of molar inclination and crossbites) tends to improve long-term dental and skeletal stability after orthognathic surgery (see Chapters 5 and 6).

History of SARPE and Segmental Osteotomies to Correct Maxillary Arch Deficiencies

The recorded history of transverse maxillary expansion dates back to the mid-1800s, when Angle reported the use of a jackscrew appliance in a 14-year-old girl to create space for a labially displaced canine.[9] This form of arch expansion was frequently used in children, adolescents, and adults until Hass reported that, after the age of 18 years, it was not possible to open the mid-palatal arch with appliance distraction forces because of the presence of bridging bone spicules across the suture and the increased rigidity of contiguous bones.[124] It is now generally accepted that RPE without "surgical assistance" is clinically successful only until the age of approximately 14 years and in the presence of open sutures. Attempting orthopedic expansion beyond this age is likely to result in the tipping and extrusion of teeth followed by dental relapse after the removal of the appliance.

The first recorded use of "surgical separation" of a fused mid-palatal suture for the management of transverse maxillary deficiency was by Brown.[49-51] Since that initial report, the clinical approach that includes the completion of maxillary osteotomies followed by orthodontic appliance expansion has continued to evolve. By the 1980s, it was recognized that a *full Le Fort I osteotomy but without down-fracture*—including the separation of the nasal septum from the maxilla and the separation of both pterygomaxillary sutures—in combination with a parasagittal palatal and interdental osteotomy (generally between the incisors) was required. The immediate activation of an in-place palatal expander in the operating room to verify the completion of the osteotomies is also required to confirm the reliability of postoperative skeletal expansion.

By the 1970s, the biologic safety of a *Le Fort I osteotomy in segments* and the ability to then three-dimensionally reconfigure the segments directly in the operating room without the need for post surgical orthodontic expansion was proven in experimental primate studies and through successful use in clinical practice (see Chapter 2). This led to questions about the value of SARPE as a first-stage procedure for the patient with a dentofacial deformity who also requires maxillary horizontal and vertical adjustments.

Interestingly, it is estimated that only a limited percentage of dentofacial deformity patients have a transverse interarch disharmony in isolation. Arch-width narrowing is generally associated with other maxillary discrepancies (e.g., vertical, horizontal, dental midline to facial midline, occlusal plane, and cant), and it is often seen in combination with deformities of the mandible. For the limited cases in which an isolated maxillary transverse deficiency does occur, the use of SARPE followed by orthodontic alignment makes intuitive sense.

For the patient to undergo a two-stage orthognathic surgical approach (i.e., first-stage SARPE followed by definitive orthognathic surgery 6 to 12 months later) for the management of a multivector maxillary deformity, significant value would have to be demonstrated. Variables to consider include the following: (1) the potential for intraoperative and postoperative complications (2) the risks of multiple rounds of general anesthesia and multiple recovery periods (3) the direct financial costs to the patient, to his or her family, and to the health care system (4) the necessary patient and family time commitment (5) the facial aesthetic effects and (6) the potential for relapse and the stability of the occlusion. Most clinicians agree that the single-stage approach (i.e., Le Fort I osteotomy in segments) has clear advantages when considering each of these variables, except for differences of opinion related to potential relapse and the stability of the occlusion. The patient described in Figure 17-13 could be considered a case that would cause one to favor a two-stage approach, because the end result is favorable. However, in retrospect, the family and the treating clinicians viewed this case as involving an inefficient approach to the correction of the individual's presenting dentofacial deformity. The two-stage approach required 1) two separate general anesthetics and recoveries 2) an extended and more elaborate course of orthodontics; and 3) an increased financial burden to the family in the form of additional surgeon and hospital fees. Also, The SARPE procedure resulted in a degree of root resorption, and the Le Fort I osteotomy (Stage II) was made more difficult by the earlier SARPE procedure (Stage I). The intraoperative view (see Figure 17-13, *F*) shows the resulting fenestrated maxillary walls after the SARPE procedure.

Complications of the SARPE Procedure: Review of the Literature

Although SARPE is a commonly considered procedure, the prevalence of postoperative complications and suboptimal results is not insignificant.[57,72,175,177,182,195,211,254,291,315,329] **Williams and colleagues** examined the prevalence of complications among patients undergoing SARPE.[329] This was a retrospective evaluation conducted on all individuals who underwent SARPE over a 4-year timeframe (2004 to 2008) at a single institution. The study sample (n = 120) included patients with a median age of 29.5 years (range, 22 to 39 years) and was comprised of 51.7% women. Postoperative complications were divided into two main categories: surgical and dental. Thirty-three patients (28%) developed surgical complications and 18 patients (15%) developed dental or periodontal problems. Asymmetric or inadequate expansion was the most frequent surgical complication, and it was found in 13.3% (16 out of 120 patients) of the study cohort. Dental or periodontal problems—including central incisor discoloration, gingival recession, and periodontal bone loss—occurred in 15% of the cohort. Two patients developed catastrophic bone defects with associated loss of the central incisors as a result of eccentric midline osteotomies followed by infections. The study confirms that major complications after SARPE are rare, whereas the incidences of asymmetric and inadequate expansion as well as dental or periodontal problems are not insignificant. These findings confirm that the SARPE procedure should not be considered as a risk-free alternative to segmental Le Fort I osteotomies.

Verlinden and colleagues reported on a large case series of individuals (n = 73 patients) undergoing SARPE with a bone-borne appliance.[315] Although most of the problems documented were related to hardware, six patients (8%) required additional surgery for the correction of an unstable occlusion or for asymmetric expansion. Among those study patients who were followed for more than 6 months, gingival recession, periodontal bone loss, a lack of interdental bone fill, and external apical root resorption were seen in more than one third of cases. **Seitz and colleagues** studied patients who were undergoing SARPE (n = 22) and found that asymmetric expansion was the most frequent surgical complication. In another review of SARPE complications, **Carmen and colleagues** reported a 28.5% incidence of significant gingival recession.[57]

Occlusal Stability and Relapse: Comparing SARPE versus Segmental Le Fort I Osteotomy

When it comes to a single-stage procedure versus a two-stage approach to the management of a complex maxillary deformity, the key aspect of occlusal stability and relapse has been reviewed in the literature and argued by clinical proponents on each side. Shortcomings in the study design of most published research add to the lack of clarity. Most studies have involved only dental casts or direct measurements of dental arch dimensions. Without the use of posteroanterior (PA) cephalograms, skeletal change cannot be differentiated from tooth movement. Another shortcoming is that most studies measure stability from the end of orthodontic treatment rather than from the point of maximum expansion. The clinical practice of over-expanding the arch to end up with a satisfactory occlusion at the end of treatment results in the underestimation of the actual relapse. With limited data points, most studies cannot differentiate skeletal relapse components from dental ones. One exception is the study by **Byloff and Mossaz,** which overcame these limitations by using pre-expansion and postexpansion PA cephalograms and dental casts as data points.[56] After SARPE, the authors observed a mean maximum expansion at the first molar of 8.7 mm, with an average of 36% (3.1 mm) relapse at the time of debanding. Only 1.3 mm (23%) of this relapse was felt to be skeletal, with the rest (77%) being dental. **Berger and colleagues** also used an improved study design and reported an average of 2.49 mm (48%) of skeletal expansion in combination with 2.4 mm (52%) of dental expansion for their patients when using a SARPE approach.[31] Two published meta studies, which were carried out in 2005 by **Koudstaal and colleagues**[167] and in 2006 by **Lagravere and colleagues,**[176] both concluded that, until that time, no good evidence existed regarding the amount of relapse after SARPE.

Chamberland and Proffit studied this controversy, and, in 2008, they published their initial research.[59] They continued to follow their patients for the long term, and they also added numbers to the study group (N = 38). Their study has been recognized for adding significant clarity to this important subject and is therefore reviewed in the next section of this chapter.

Skeletal Stability and Relapse of SARPE: Review of a Benchmark Study

A prospective observational study was carried out by **Chamberland and Proffit** to review the SARPE outcomes in 38 consecutive patients between the ages of 15 and 54 years, with an observation period that extended to 2 years after the completion of treatment.[60] The data collected by these authors included measurements taken from both dental casts and PA cephalograms at the following specific time intervals:

- Before SARPE or any active orthodontic alignment
- After SARPE and at the completion of orthodontic expansion
- At the removal of the orthodontic expander (i.e., approximately 6 months after SARPE and the completion of the orthodontic goals)
- Before the final orthognathic procedure (if any was planned)
- After the final orthognathic surgery and at the end of orthodontic treatment
- 2 years after the completion of treatment

All study patients had a transverse discrepancy of 5 mm or more and were beyond the level of maturity at which palatal expansion without surgery would be possible. The surgical technique involved all bone cuts required for a Le Fort I osteotomy, including the separation of the pterygoid junctions, the nasal septum, and the mid-palatal suture as well as an osteotomy between the central incisors. During surgery, the expansion device was activated to achieve a 1- to 1.5-mm separation of the maxillary central incisors. After latency (7 days), the device was activated twice daily (0.5 mm/day). The patients were monitored twice weekly until the planned expansion was achieved 12 to 20 days later. All patients were expanded 2 mm beyond the desired final position. The expansion device was kept in place for approximately 6 months after the completion of orthodontic goals.

Interestingly, the research data confirm that almost the entire measured relapse was dental rather than skeletal. At 49 months after the SARPE procedure, the maintained expansion at the first molars had relapsed to approach the skeletal expansion (i.e., 4.6 mm total molar expansion [dental and skeletal] as compared with 3.6 mm skeletal expansion). The skeletal expansion that was measured at both the jugula and the nasal cavity was statistically stable.

All patients were maximally expanded 2 mm beyond the desired final position on the basis of the researchers' assumptions that a degree of relapse was inevitable. This overcorrection ensured that, despite a measured dental relapse of 30%, none of the patients showed posterior crossbite at the completion of treatment. One can conclude that, despite retention attempts, over the long term the teeth drift back into the basal bone (see Chapters 5 and 6).

The authors also compared their relapse and stability results with other published SARPE studies. Their measured 30% relapse rate was found to be less than the 36% relapse reported by Byloff and Mossaz.[56] Alternatively, their 30% documented relapse rate was higher than that reported by either Berger and colleagues[31] or Pogrel and colleagues.[238] As previously stated, most SARPE studies—including these two—do not report relapse from a starting point of maximal expansion. However, not doing so will underestimate the level of actual relapse and may explain the differences reported.

Chamberland and Profit showed that, when a SARPE procedure is carried out with the use of optimal surgical and orthodontic techniques, maxillary expansion that is about 47% skeletal and 53% dental can be expected.[59,60] The skeletal expansion that occurred with SARPE followed by strict orthodontic maintenance mechanics for approximately 5 months proved to be statistically stable. The overall relapse rate (30%) was almost totally attributable to lingual retraction (dental relapse) of the posterior teeth. As stated, the authors recommend a 2-mm excess expansion in anticipation of dental relapse. For example, in the case of a desired 8-mm first molar expansion, 10 mm of surgical expansion at the molars is recommended. The researchers documented the advantage of compensating for the inevitable buccal tipping of the posterior maxillary teeth during the expansion phase followed by an inevitable lingual dental relapse after the device is removed. Approximately 25% of their patients had more than 3 mm of dental relapse, whereas 42% had between 1 mm and 3 mm. A full 66% of patients experienced more than 2 mm of dental relapse over the long term (i.e., 2 years after debonding).

Stability and Relapse: Comparing SARPE in Adults versus RPE in Prepubertal Children

The literature confirms that, in the prepubertal child or the adolescent with an open palatal suture, a loss of about one third of the maximum expansion occurs across the first molars after non-surgical RPE. PA cephalograms performed for prepubertal patients with palatal implant markers who underwent RPE demonstrate that approximately 50% of the expansion achieved is skeletal, with the remainder being dental. This can be compared to Chamberland and Proffit's adult SARPE data.[59,60] Those authors demonstrated a mean of 3.47 mm of skeletal expansion and 2.25 mm of dental expansion (i.e., 5.12 mm of total expansion) at the first molars. They then documented a 30% relapse, the majority of which was dental. Therefore, a comparable 30% overall relapse in both the SARPE (adult) group and the RPE (prepubertal) group was found to occur. Interestingly, in the SARPE group, the maintenance of skeletal expansion was greater than that achieved in the RPE group.

Stability and Relapse in Adults: Comparing SARPE versus Segmental Le Fort I Osteotomies

The best data regarding stability after transverse expansion with segmental Le Fort I osteotomies were reported for 32 patients by Phillips and colleagues.[215] Chamberland and Proffit compared the segmental Le Fort I osteotomy group of Phillips and colleagues to their SARPE study patients.[59,60] They used a subgroup of Phillips and colleagues' patients who had undergone levels of maxillary expansion that were equivalent to those of their own SARPE patients. A comparison of the findings demonstrated the following: 1) the mean relapse across the first molars was greater for the Le Fort I group, but the difference was not statistically significant; and 2) the mean relapse across the canines was greater for the SARPE group and was statistically significant.

With reference to the SARPE (two-stage) approach versus the Le Fort I segmental (single-stage) approach for the correction of complex maxillary deformities (i.e. combination of arch-width, vertical, and horizontal deformities), the author's conclude:[59,60]

- Current data do not support the conclusion that SARPE procedures produce more stable expansion than Le Fort I segmental osteotomies.
- Published data regarding both PA cephalograms and measurements of dental models confirm the potential for postoperative relapse that is primarily dental rather than skeletal after transverse maxillary

expansion (i.e., RPE, SARPE, or Le Fort I segmental osteotomies).

- Relapse after the arch width initially achieved by SARPE is comparable to that of other expansion procedures (i.e., segmental Le Fort I osteotomy in adults and RPE in children).
- Published data show that, with properly executed SARPE and a strict maintenance protocol for approximately 6 months, the relapse is almost entirely dental (i.e., 33% dental relapse). At the end of treatment, there is, on average, a net expansion of 67% of the total change.
- With non-surgical expansion carried out in growing individuals (i.e., RPE), the expectation is that only 50% of the total change will be skeletal. No data from sequential PA cephalograms exists for Le Fort I segmental expansion.
- Given the similarity of relapse in intermolar width between SARPE and Le Fort I segmental techniques, routine overcorrection and strict maintenance for 6 months after surgery should be considered part of the protocol.
- When surgery to reposition the maxilla vertically or anteroposteriorly is also required, the routine performance of a preliminary SARPE procedure followed later by a Le Fort I osteotomy with the intention of obtaining better transverse stability does not appear to be warranted.
- According to published literature, the decision to use a two-stage surgical approach (i.e. first stage SARPE) versus a single-stage Le Fort I segmental surgical approach should not be based on the expected stability of the transverse expansion. Instead, it should be based on the risk and morbidity of two surgeries versus the risk and morbidity of a one-stage multisegmented Le Fort I osteotomy for arch expansion and the other necessary vertical or anteroposterior changes required for the correction of the individual's specific dentofacial deformity.
- Clinicians should also take into account that the SARPE procedure will result in areas of fibrous union and defects at the maxillary osteotomy sites. If a Le Fort I is later required to complete the reconstruction, the previous SARPE procedure may add to the complexity of the operation (see Fig. 17-13).

Conclusions

There are inherent challenges to both the orthodontic movement of teeth within the alveolar process and the surgical repositioning of the jaws within the facial soft-tissue envelope. Such challenges include the orthodontist's treatment philosophy; the mechanics used to reposition the teeth; the surgeon's treatment philosophy; and the techniques used to complete the osteotomies and secure them. Other important factors include the initial surgical healing requirements, which take into account patient-specific health-related factors, as well as the difficulties associated with the long-term maintenance of the mechanically relocated teeth, jaws, and jaw segments.

Despite the potential for skeletal and dental relapse, when sound biomechanical and aesthetic principles are followed, the frequent patterns of dentofacial deformity and their associated malocclusions can be safely and reliably corrected and maintained in most cases.

Bone Grafting: Definitions and Options

During maxillofacial surgery, grafting is a procedure that replaces missing structures with tissues from the patient's own body or with artificial, synthetic, or natural substitutes.[24,33,40,50,56,60,62,69-71,78,106,111,112] It is estimated that more than 500,000 bone-grafting procedures are performed annually in the United States, and these numbers easily double globally. Approximately half of the procedures that involve grafts relate to spinal fusion. The exact number of grafts used in head and neck reconstruction is not known, but it is significant.

Bone grafting is possible because bone—unlike most other biologic tissues—has the ability to regenerate completely if it is provided with space into which it can grow.[3-5,7,13,29,34,49,64,65,83,125-128] As native bone grows, it will generally replace any resorbable graft material in its path, which results in a fully integrated region of new bone. The biologic mechanisms that provide a rationale for bone grafting are osteoconduction, osteoinduction, and osteogenesis.

Osteoconduction occurs when the graft material serves as a scaffold that facilitates new growth from the native bone (Fig. 18-1, *A*). Osteoblasts from the margin of the defect use the graft material as a framework upon which to spread and generate new bone. The selected graft material for the management of a bone defect should at the very least be osteoconductive.

Osteoinduction involves the stimulation of osteoprogenitor cells to differentiate into osteoblasts that then begin new bone formation (Fig. 18-1, *B*). The most widely studied types of osteoinductive cell mediators are bone morphogenic proteins (BMPs). A bone graft material that is both osteoconductive and osteoinductive will serve as a scaffold for existing osteoblasts, and it will also stimulate the formation of new osteoblasts, thereby theoretically promoting the faster integration of the graft.

Osteogenesis occurs when vital osteoblasts that originate from the bone graft material itself contribute to new growth along with bone growth generated via the mechanisms of osteoinduction and osteoconduction. Fresh autogenous bone graft has the capability of supporting new bone growth by all three means (i.e., osteogenesis, osteoinduction, and osteoconduction). Because all three mechanisms may not be required at the particular recipient site to establish successful healing, it should be possible in many circumstances to select a non-autogenous graft, thereby avoiding the need for harvesting donor bone from the patient and still achieving success.

The sheer volume of bone grafting procedures carried out in the United States and throughout the world has created a relative shortage of available musculoskeletal donor tissue that is traditionally used for reconstructive autografts and allografts. This opportunity has stimulated corporate interest in supplying what is seen as a growing market for bone replacement materials. Currently, these graft alternatives are subjected to varying degrees of regulatory scrutiny; their true effectiveness in patients is not known until validated clinical trials are eventually carried out.

In general, it is known that osteoconductive materials work well when filling defects of non-critical size that would normally be expected to heal. However, when more

NFB presents features of mature bone, with well-organized lamellae and numerous small osteocytic lacunae. **B,** Osteoinduction. Peripheral region of the graft at 10 days. New bone formation, with primary bone tissue from the bone graft *(BG)* fragment and the parietal bone. **A** *from Acocella A, Bertolai R, Nissan J, Sacco R: Clinical, histological and histomorphometrical study of maxillary sinus augmentation using cortico-cancellous fresh frozen chips.* J Craniomaxillofac Surg *39:192–199, 2011.* **B** *from Esteves JC, Borrasca AG, Aranega AM, et al: Histomorphometric analysis of the repair process of autogenous bone grafts fixed at rat calvaria with cyanoacrylate.* J Appl Oral Sci *19:529–534, 2011.*

challenging defects are present, either fresh autologous bone graft or grafts with an osteoinductive agent appear to be necessary or are at least preferable for favorable healing.

Types of Bone Grafts

Bone Autografts

Fresh autogenous cancellous and corticocancellous bone are benchmark graft materials that allograft and bone substitutes attempt to match in their in vivo performance.[2,25,117-124] They incorporate all of the aforementioned properties, and they have no associated risk of viral transmission. They are incorporated into surrounding bone through creeping substitution. Unfortunately, the availability of an autograft for a specific need may be limited, and the harvest may be associated with donor site morbidity.[10]

Bone Allografts

The advantages of bone allografts that are recovered from deceased human donor sources include their availability in various shapes and sizes, the avoidance of the need to sacrifice host structures, and the lack of donor-site morbidity. Bone allografts are distributed through regional tissue banks and by a variety of reputable orthopedic medical device companies. The grafts are not without controversy, particularly because of their association with the transmission of infectious agents. It is essential to know the tissue bank provider's methods of handling the allografts to understand infectious disease issues and the potency of the graft material. Allografts should be compared with autogenous bone grafts with reference to their structural strength, osteoconduction, osteoinduction, and osteogenesis.

Bone Graft Substitutes

The ideal bone graft substitute is biocompatible, bioresorbable, osteoconductive, osteoinductive, structurally similar to bone, easy to use, and cost-effective. A growing number of bone graft alternatives are commercially available for orthopedic and, to a lesser extent, head and neck use. They are used in the reconstruction of cavitary bony deficiencies (i.e., interpositional defects) and for augmentation purposes.

Not all bone graft alternatives perform equally well. This presents a challenge to the orthognathic surgeon. It is important to appreciate the varied but repetitively seen graft-healing environments related to orthognathic surgery, including the following: (1) an interpositional defect at the chin osteotomy site; (2) an interpositional defect at the Le Fort I osteotomy site; (3) an interpositional defect at the ramus of the mandible osteotomy site; (4) the augmentation needs of the chin, the angle of the mandible, the zygomas, the perinasal area, and the infra-orbital rim; (5) a radiated tissue bed that requires osteotomy site healing; and (6) the proximity of the Le Fort I osteotomy site to the maxillary sinus. Each recipient environment will present with different graft-healing needs. Therefore, the validation of any bone graft alternative in one clinical site will not necessarily predict its performance in another location.

The clinician should seek a high burden of proof when using clinical or preclinical studies to justify the use of an osteoinductive graft material and the choice of one alternative over another. Only human trials can best determine the efficacy of a bone graft substitute and its site-specific effectiveness. Whenever feasible, surgeons should practice evidence-based medicine and tailor the treatment of their patient according to published medical literature and the levels of evidence claimed.

U.S. Food and Drug Administration approvals of bone graft substitutes for human use include the following:

The use of premarket-approved rh-BMP-2 (Infuse Bone Graft; Medtronic, Minneapolis, Minn) as an autograft

replacement for spinal fusion and the treatment of open tibia fractures. This substance has also been approved for maxillary sinus augmentation and localized alveolar ridge augmentation.

The use of rh-BMP-7 (OP-1 Implant; Olympus Biotech, Hopkington, Mass) as a humanitarian device. This substance has been approved as an autograft substitute for the non-union of long bones.

The use of rh-BMP-7 (Op-1 Putty; Olympus Biotech, Hopkington, Mass) as a humanitarian device alternative to autograft in compromised patients. This substance is approved for patients who require revision posterolateral lumbar spinal fusion or for those in whom autologous bone and bone marrow recovery (i.e., harvesting) are not feasible or are not expected to promote fusion.

The specific applications of bone substitutes, as described previously, have demonstrated clinically useful osteoinductive capabilities in humans. They have paved the way for broader clinical applications in the future. The recommended methods for the clinical application of these bone substitutes include direct placement into the surgical site, but the results have been more promising when the growth factors have been administered in combination with substrates to facilitate timed-release delivery or to provide a material scaffold for bone formation.

Please review the following salient points when considering the use of bone graft substitutes during orthognathic surgery:

- Fresh autogenous cancellous bone and, to a lesser extent, cortical bone are the benchmark graft materials. Their shortcomings include limited availability, donor site morbidity, and the potential for resorption.
- The advantages of allogenic bone include its availability in various sizes and shapes as well as the avoidance of host donor harvesting. The transmission of infection (particularly of human immunodeficiency virus) has been virtually eliminated as a concern when the grafts are properly treated.
- The ideal bone graft substitute is biocompatible, bioresorbable, osteoconductive, osteoinductive, structurally similar to bone, easy to use, and cost-effective. Bone substitute products are currently available on the market. They vary with regard to their composition and their claimed mechanism of action.
- U.S. Food and Drug Administration approvals of specific uses of recombinant human growth factors (i.e., rh-BMP-2 and rh-BMP-7) for the spine and the long bones have been made on the basis of demonstrated bone repair in human trials. Approved head and neck applications are limited but are likely to increase.
- The orthognathic surgeon has choices in the realm of bone grafting. Selection should be based on reasonable burdens of proof. Examining the products' claims and whether such claims are supported by preclinical and clinical studies for the specific sites to be used during clinical practice should be considered.

Grafting Interpositional Defects and Gaps of the Mandible and the Maxilla

Autogenous Iliac (Particulate Cancellous) Graft Donor Site (Video 8)

Iliac (hip) particulate cancellous bone remains the preferred graft material for the management of congenital cleft defects of the alveolus, the palate, and the floor of the nose.[1,9,12,15,26,28,46-48,52,63,66,77,82,90,115] This is especially true when the canine tooth is expected to erupt through the graft (i.e., cleft defect); when a tooth will be orthodontically moved into the grafted site; or when a dental implant will later be placed (Fig. 18-2). The cleft defect that requires a graft may be on one side (i.e., with unilateral cleft lip and palate) or on both sides (i.e., with bilateral cleft lip and palate). Previous attempts at grafting a bone deficiency may have failed as a result of an unsuitable graft material being selected; a soft-tissue deficiency or poor flap management; or inadequate postoperative management or patient cooperation (see Chapters 32 and 33).

Donor site discomfort in the anterior iliac region is generally caused by the injury or contusion of the surrounding muscles on the medial (i.e., external oblique, internal oblique, and rectus abdominis) and lateral (i.e., medial gluteus) sides of the bone.* In a thin individual with a minimal fat layer and without baseline ankle, knee, or lumbar region arthritis or myalgia who is relatively young (i.e., <50 years), only minimum discomfort should occur. However, there are reports of complications associated with anterior iliac crest graft harvesting, including gait disturbance, paresthesia, superficial infections, hematoma, poor cosmesis, and chronic donor site pain.[6,20,41,42,53,57,81,92,103-105,110,113,114,131] The experienced surgeon can harvest the graft rapidly and efficiently. There is no need for the placement of a drain, minimal blood loss (i.e., <50 cc) is expected, and the head and neck region will have been simultaneously prepped and draped.

Step-by-Step Approach (Fig. 18-3)

Preparation and Draping

- An endotracheal tube is placed and secured in accordance with the patient's head and neck reconstruction needs.
- Ophthalmic ointment and corneal shields are placed for eye protection.
- The patient is supine on the operating room table.
- The patient's arm is tightly tucked to his or her side.
- Betadine solution is used for both hip and head and neck preparation.

• **Figure 18-2** A child was born with unilateral cleft lip and palate and underwent arch expansion orthodontic treatment. This was followed by autogenous iliac bone grafting and fistula closure during the mixed dentition. **A,** Intraoperative view after the elevation of the mucogingival flap indicating the extent of the cleft defect. **B,** Harvested autogenous cancellous iliac graft used to fill the cleft defect. **C,** Occlusal view early after surgery. **D,** Later occlusal view with the early eruption of the canine. **E,** Occlusal and palate view after the eruption of the permanent canine through the bone graft. The canine and the other posterior teeth are orthodontically guided anteriorly to close the cleft and dental gap in the region of the congenitally missing lateral incisor. **F,** Periapical radiograph indicating normal alveolar ridge formation after the eruption of the canine through the bone-grafted cleft site.

Incision marked

Incision through skin

Scissor dissect to cartilage

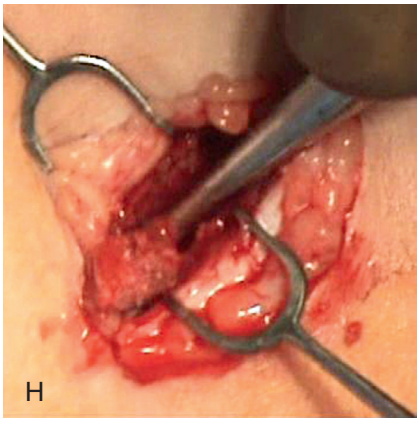
Incision through cartilage cap

• **Figure 18-3** Autogenous iliac (particularly cancellous) graft donor site harvesting. **A,** The planned incision is parallel and 1 cm lateral to the iliac crest. The incision starts 1 cm posterior to the anterior superior iliac spine. **B,** After the injection of local anesthesia, the incision is carried out through the skin. **C,** Scissors dissection continues through the subcutaneous tissue and the superficial and deep fascia while avoiding the cutting and contusion of the gluteus muscle laterally or the abdominal oblique and transverse abdominis muscles medially. **D,** With a knife, the cartilaginous cap is split down the center directly over the crest and down to the marrow cavity.

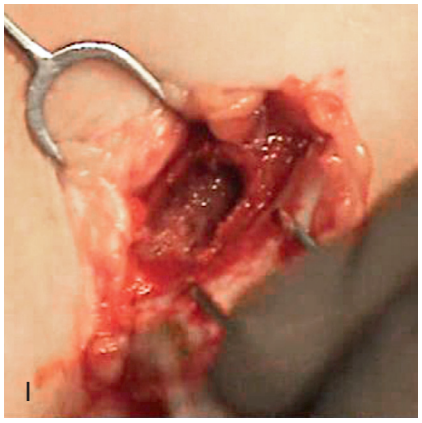
Incision down to marrow

Elevation of cartilage flap

Flaps curette



Curette used to remove cancellous bone

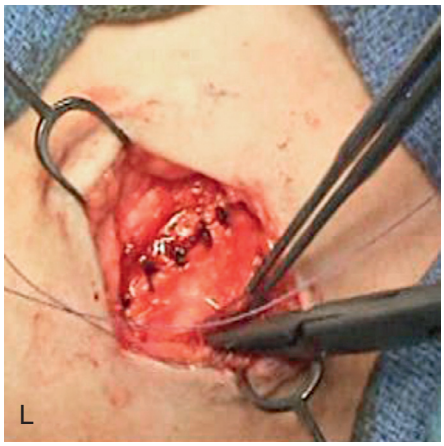


Defect in ilium

Cancellous bone harvested

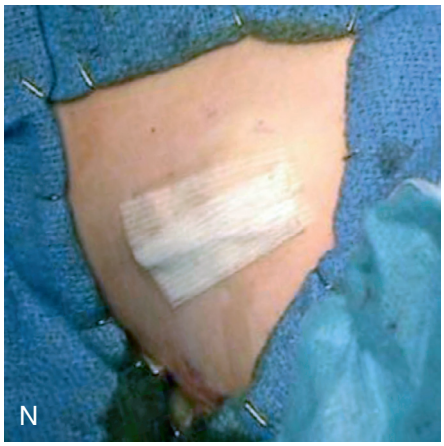
• **Figure 18-3, cont'd** **E,** With a knife, perpendicular relaxing incisions are completed through the cartilage at either end of the main incision. **F,** With a periosteal elevator, each half of the cartilaginous cap (i.e., medial and lateral) is elevated off of the underlying marrow space. **G,** The cancellous marrow bone is now exposed. **H,** Exposed cancellous bone is harvested with curettes. **I,** With the necessary cancellous bone harvested, a defect in the marrow space can be seen. **J,** Harvested cancellous marrow bone to be used for reconstruction.

Cartilage cap sutured



Fascial layer sutured

Skin closure



Dressing applied

• **Figure 18-3, cont'd K,** The cartilaginous cap is repositioned back in place with interrupted ties (3-0 Vicryl). **L,** The deep and superficial fascia layers are closed with interrupted suture ties (3-0 Vicryl). **M,** Subdermal closure is performed with interrupted suture ties (4-0 Vicryl). The skin is closed with subcuticular running suture (5-0 Monocryl). **N,** Steri-Strips and then an occlusive dressing (Tegaderm) are placed over the skin.

- At the hip, the patient is prepped halfway down the thigh, to the groin, across the abdominal midline, up to the rib cage, and posterior down the side of the buttock.
- Draping is completed, with limited exposed skin left around the planned incision site.

Surgical Markings

- The planned hip region incision (i.e., 3 cm) is located and marked with a surgical pen before prep and draping.
- The planned incision is parallel and 1 cm lateral to the iliac crest. The incision starts 1 cm posterior to the anterior superior iliac spine.

Local Anesthesia

- Xylocaine (1% with 1:100,000 epinephrine) is injected below the skin, directly over the surgical marking, and down to the periosteum over the iliac crest.

Skin Incision and Flap Elevation

- The incision is carried through the skin, the subcutaneous tissue, and the superficial and deep fascia directly over the iliac crest where the graft is to be harvested.
- The cutting or contusion of the gluteus muscle laterally or of the abdominal oblique and transverse abdominis muscles medially is to be avoided. Injury to these muscles when approaching the iliac crest should be avoided, because this is the primary cause of buttock and abdominal wall discomfort after surgery.

Graft Harvesting

Cartilage Cap Over Crest (Patient Typically <12 Years Old)

- If a cartilaginous cap remains over the crest, it is split down the center directly over the crest and down to the marrow cavity. Perpendicular relaxing incisions are completed through the cartilage at either end of the main incision. This allows for the lifting of each half of the

cartilage cap (i.e., medial and lateral) off of the underlying marrow space. The lifting of the vascularized cartilage flaps is accomplished with a periosteal elevator.
- The exposed cancellous bone is then harvested with curettes.

No Cartilage Cap Over Crest (Patient Typically >12 Years Old)

- When the iliac crest is mature, no cartilaginous cap remains. In this case, a window of cortical bone is removed from the medial aspect of the crest and down the medial plate for approximately 2 cm. This is an efficient method for the exposure of the medullary cavity.
- The subperiosteal dissection of the medial crest and down the medial plate is followed by the placement of a toed-out retractor down the medial plate.
- The removal of the cortex is facilitated with the following: 1) an oscillating saw with a short fan blade on a long shaft to cut through the cortex of the medial plate at the inferior aspect; 2) an oscillating saw with a wide fan blade on a short shaft to cut through the cortex of the medial crest; and 3) a reciprocating saw with a short, straight blade to cut through the cortices of the medial plate to connect the other two cuts.
- The removal of the window of cortical bone is then easily accomplished with the use of a chisel and a mallet.
- With the window of cortical bone removed, cancellous marrow is harvested with curettes.
- The removed cortical bone may also be chopped or used as an intact cortical graft. There is no advantage to replacing the small cortical bone segment, because the strength of the crest has not been compromised. The bone defect will not be visible or palpable through the closed skin wound. The removed marrow and cortical bone regenerate themselves.

Wound Closure

- After adequate graft is harvested, bone wax is used for hemostasis. The bone wax is not used to fill the cavity; rather, a thin layer is placed directly over the bleeding medullary surfaces. Interestingly, the wax does not prevent the regeneration of bone that will fill the cavity.
- If present, the cartilaginous cap is repositioned and sutured back into place with interrupted ties (3-0 Vicryl). If a cap is not present, then the overlying periosteum is closed with interrupted ties (3-0 Vicryl).
- The deep and superficial fascia layers are closed with interrupted suture ties (3-0 Vicryl).
- Subdermal closure is performed with interrupted suture ties (4-0 Vicryl).
- The skin is closed with subcuticular running suture (5-0 Monocryl).

Placement of Dressing

- The skin surface is cleaned with saline. It is then dried, and benzoin is applied.
- A limited number of Steri-Strips are placed directly over the closed wound.
- A small piece of cut gauze is placed directly over the Steri-Strips.
- An occlusive dressing (e.g., Tegaderm) is placed over the skin.

Postoperative Care

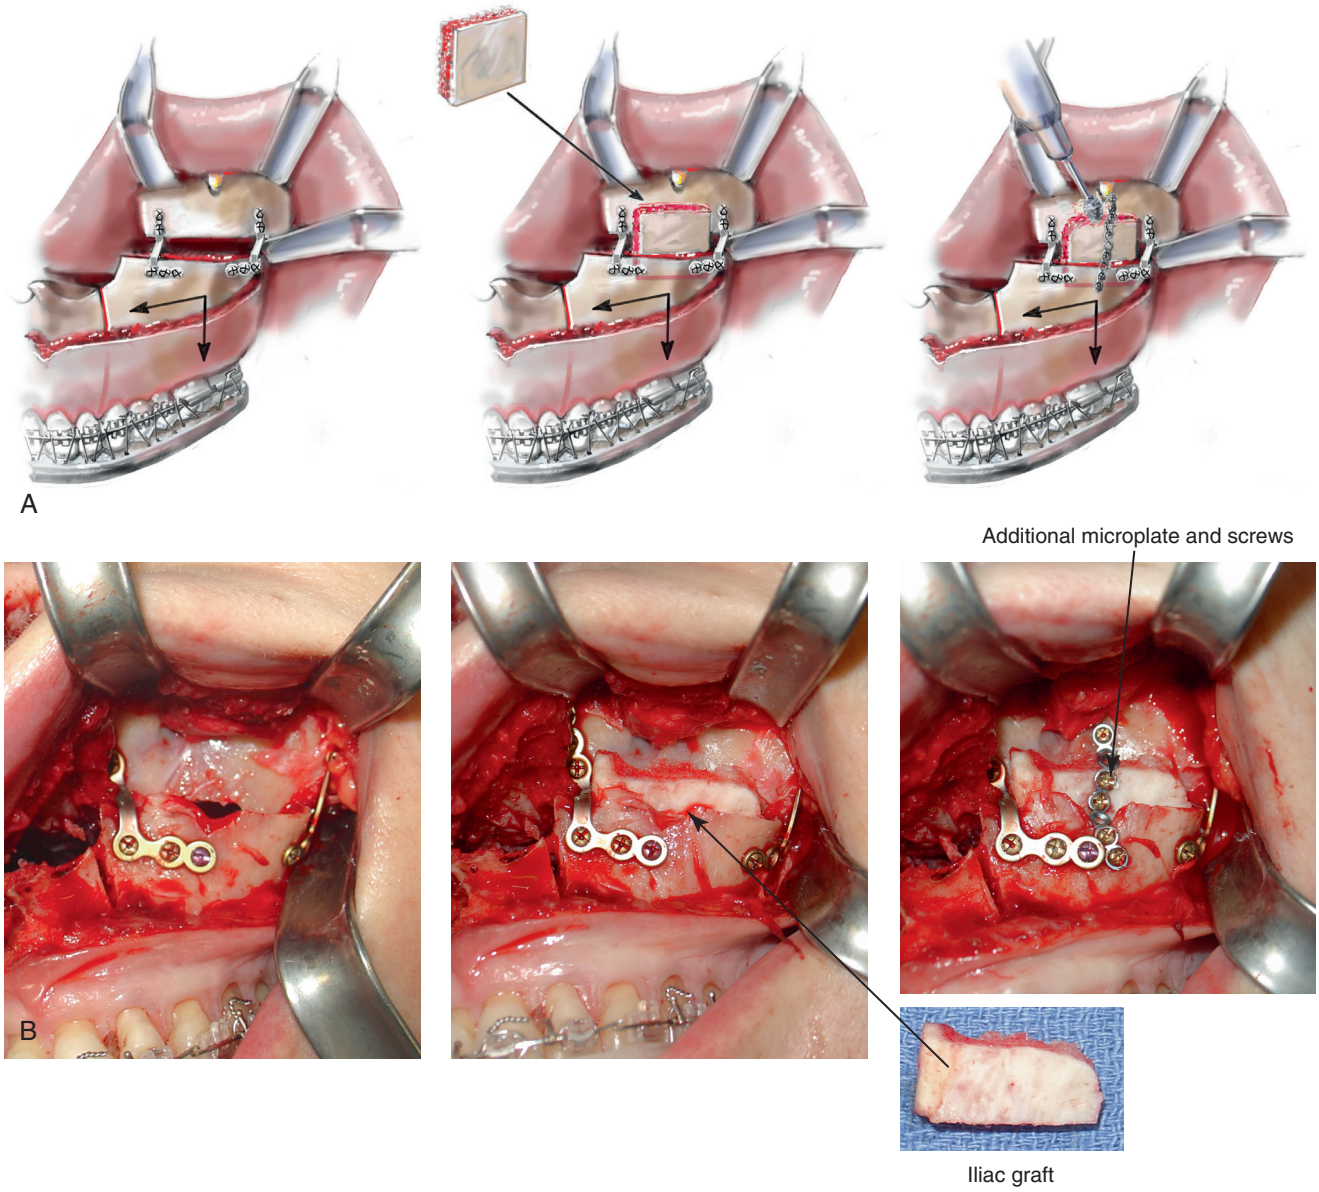
- The patient may shower without concern about moisture getting on the occlusive dressing that is covering the wound.
- The dressing remains intact for approximately 7 to 10 days.
- After the dressing is removed, no additional bandages are placed.

Autogenous Iliac (Corticocancellous Bloc) Graft Donor Site (Video 9)

When a Le Fort I osteotomy with significant horizontal advancement and vertical lengthening is carried out, an interpositional defect (i.e., dead space) is created. Despite rigid plate and screw fixation of the repositioned maxilla, inadequate bone contact may jeopardize successful healing (e.g., fibrous union; see Chapter 16) or leave the upper jaw prone to skeletal relapse (see Chapter 17). The advantage of placing an interpositional graft is sometimes obvious and at other times borderline. When an interpositional graft is deemed necessary, I prefer to use either autogenous or allogenic iliac bone.[107] A crafted corticocancellous anterior iliac (hip) graft is interposed between the pyriform and the zygomatic titanium plates that are used to secure the upper jaw in its new location (Fig. 18-4). The graft is tightly wedged between the advanced and lengthened anterior maxillary wall and the more posterior baseline maxillary wall. Any sharp edges of the inset graft are smoothed using a rotary drill with a watermelon bur. The graft is then fixed in place with an additional titanium plate and screws.

Another indication for a corticocancellous bloc graft is when a ramus osteotomy (e.g., an inverted L or straight horizontal osteotomy) is completed. After the proximal segment is seated with the condyle in the glenoid fossa (i.e., the terminal hinge position) and the distal mandible is secured to the maxillary teeth via intermaxillary fixation, a significant interpositional gap may remain. In these circumstances, a crafted corticocancellous iliac graft can be tightly interposed between the proximal and distal segments with additional cancellous bone packed into the remaining dead space. Rigid plate and screw fixation of the osteotomy segments and the graft is always required (see Chapter 28).

When an anterior maxillary or mandibular segmental alveolar defect requires reconstruction (e.g., after trauma or tumor resection), a crafted corticocancellous anterior iliac graft is generally preferable to other options. After successful graft healing (i.e., 4 to 6 months), dental rehabilitation including implant and crown placement may follow (see Chapter 35).[2]



• **Figure 18-4** When the extent of horizontal advancement and vertical lengthening of the maxilla after Le Fort I osteotomy are judged to be significant, then an interpositional bone graft may be required and beneficial for the achievement of precise healing. In these circumstances, I prefer to use either autogenous or allogenic iliac bone graft. A bloc of corticocancellous bone is crafted and tightly wedged into the gap on each side. Each graft is inset in between the pyriform rim and zygomatic buttress titanium plates. An additional plate is then contoured to extend from the anterior maxilla above, across the graft, and then onto the alveolar process of the anterior maxilla. Titanium screws (1.2 mm in diameter) are then used to secure the plate to the bone. **A,** Illustrations and **B,** intraoperative views of interpositional corticancellous iliac graft in a Le Fort I osteotomy site.

Donor site discomfort in the anterior iliac region is generally caused by the injury or contusion of the surrounding muscles on the medial (i.e., external oblique, internal oblique, and rectus abdominis) and lateral (i.e., medial gluteus) sides of the bone.* In a thin individual with a minimal fat layer and without baseline ankle, knee, or lumbar region arthritis or myalgia who is relatively young (i.e., <50 years old), only minimum muscle contusion and discomfort should occur. However, there are reports of complications associated with anterior iliac crest graft harvesting, including gait disturbance, paresthesia, superficial infections, hematoma, poor cosmesis, and chronic donor site pain.[6,20,41,42,53,57,81,92,103,104,105,110,113,114,131] The experienced surgeon can harvest the graft rapidly and effectively. In general, there is no need for the placement of a drain, minimal blood loss (i.e., <50 cc) is expected, and the head and neck region will have been simultaneously prepped and draped.

*Reference 8, 10, 16, 21-23, 35, 36, 51, 54, 55, 58, 61, 72-75, 80, 88, 100, 130, 143, 138

Step-by-Step Approach (Fig. 18-5)

Preparation and Draping

- An endotracheal tube is placed and secured in accordance with the patient's head and neck reconstruction needs.
- Ophthalmic ointment and corneal shields are placed for eye protection.
- The patient is supine on the operating room table.
- The patient's arm is tightly tucked to his or her side.
- Betadine solution is used for both hip and head and neck preparation.
- At the hip, the patient is prepped halfway down the thigh, to the groin, across the abdominal midline, up to the rib cage, and posterior down the side of the buttock.
- Draping is completed, with limited exposed skin left around the planned incision.

Surgical Markings

- The planned hip region incision (i.e., 3 cm to 4 cm) is located and marked with a surgical pen before preparation and draping.
- The planned incision is parallel and 1cm lateral to the iliac crest. It starts just posterior to the anterior superior iliac spine.

Local Anesthesia

- Xylocaine (1% with 1:100,000 epinephrine) is injected below the skin, directly over the surgical marking, and down to the periosteum over the iliac crest.

Skin Incision and Flap Elevation

- The incision is carried through the skin, the subcutaneous tissue, and the superficial and deep fascia directly over the iliac crest where the graft is to be harvested.
- The cutting or contusion of the gluteus muscle laterally or of the abdominal oblique and transverse abdominis muscles medially is to be avoided. Injury to these muscles when approaching the iliac crest is the primary cause of buttock and abdominal wall discomfort after surgery.

Graft Harvesting

- With the use of a knife (no. 15 blade), the periosteum is scored directly over the midline of the crest from just posterior of the anterior superior iliac spine. The incision continues posteriorly for a distance that is dependent on the extent of exposure required for the planned graft.
- Subperiosteal dissection of the medial crest and down the medial plate continues. A toed-out retractor is placed down the medial plate.
- The efficient removal of a bloc of corticocancellous bone graft is accomplished using an oscillating saw (with a short fan blade on a long shaft and a wide fan blade on a short shaft) and a reciprocating saw (with a short, straight blade) to cut through all four bordering cortical walls.
- The corticocancellous bloc graft is then removed from the medial aspect of the crest and down the medial plate. The length of the graft along the crest and its depth into the medullary cavity are variable, depending on the patient's reconstructive needs.
- The actual removal of the corticocancellous bloc is accomplished with the use of a 10-mm chisel and a twisting motion to fully separate the graft.
- With the bloc graft removed, additional cancellous marrow is harvested with curettes, as needed.
- The strength of the crest and of the ilium as a whole should not be compromised by the bloc graft removal. In general, the bone defect will not be detectable through the closed skin wound, because the lateral aspect of crest is preserved. The removed marrow and the cortical bone will regenerate, often with greater than normal thickness.

Wound Closure

- After adequate graft is harvested, bone wax is used for hemostasis. The bone wax is not used to fill the cavity; rather, a thin layer is placed directly over the bleeding medullary surfaces. The wax should not prevent bone regeneration.

Handheld instruments

Incision marked and local anesthesia injected

• **Figure 18-5** Intraoperative views of the harvesting of autogenous iliac corticocancellous bone. **A,** The basic handheld instruments that are used to harvest the graft. **B,** The planned incision is parallel and lateral to the iliac crest. It starts just posterior to the anterior superior iliac spine. Local anesthesia is injected below the skin directly over the surgical marking and down to the periosteum over the iliac crest.

Suturing of skin

Dressing in place

• **Figure 18-5, cont'd** **O,** The periosteum is closed with interrupted suture ties (3-0 Vicryl). **P,** After closing the deep and superficial fascia layers with interrupted sutures (3-0 Vicryl), subdermal and then subcuticular closure are accomplished (5-0 Monocryl). **Q,** Steri-Strips and then an occlusive dressing (Tegaderm) are placed over the skin.

- The periosteum is closed with interrupted suture ties (3-0 Vicryl).
- The deep and superficial fascia layers are closed with interrupted suture ties (3-0 Vicryl).
- Subdermal closure is performed with interrupted suture ties (4-0 Vicryl).
- The skin is closed with subcuticular running suture (5-0 Monocryl).

Placement of Dressing

- The skin surface is cleaned with saline. It is then dried, and benzoin is applied.
- A limited number of Steri-Strips are placed directly over the closed wound.
- A small piece of cut gauze is placed directly over the Steri-Strips.
- An occlusive dressing (e.g., Tegaderm) is placed over the skin.

Postoperative Care

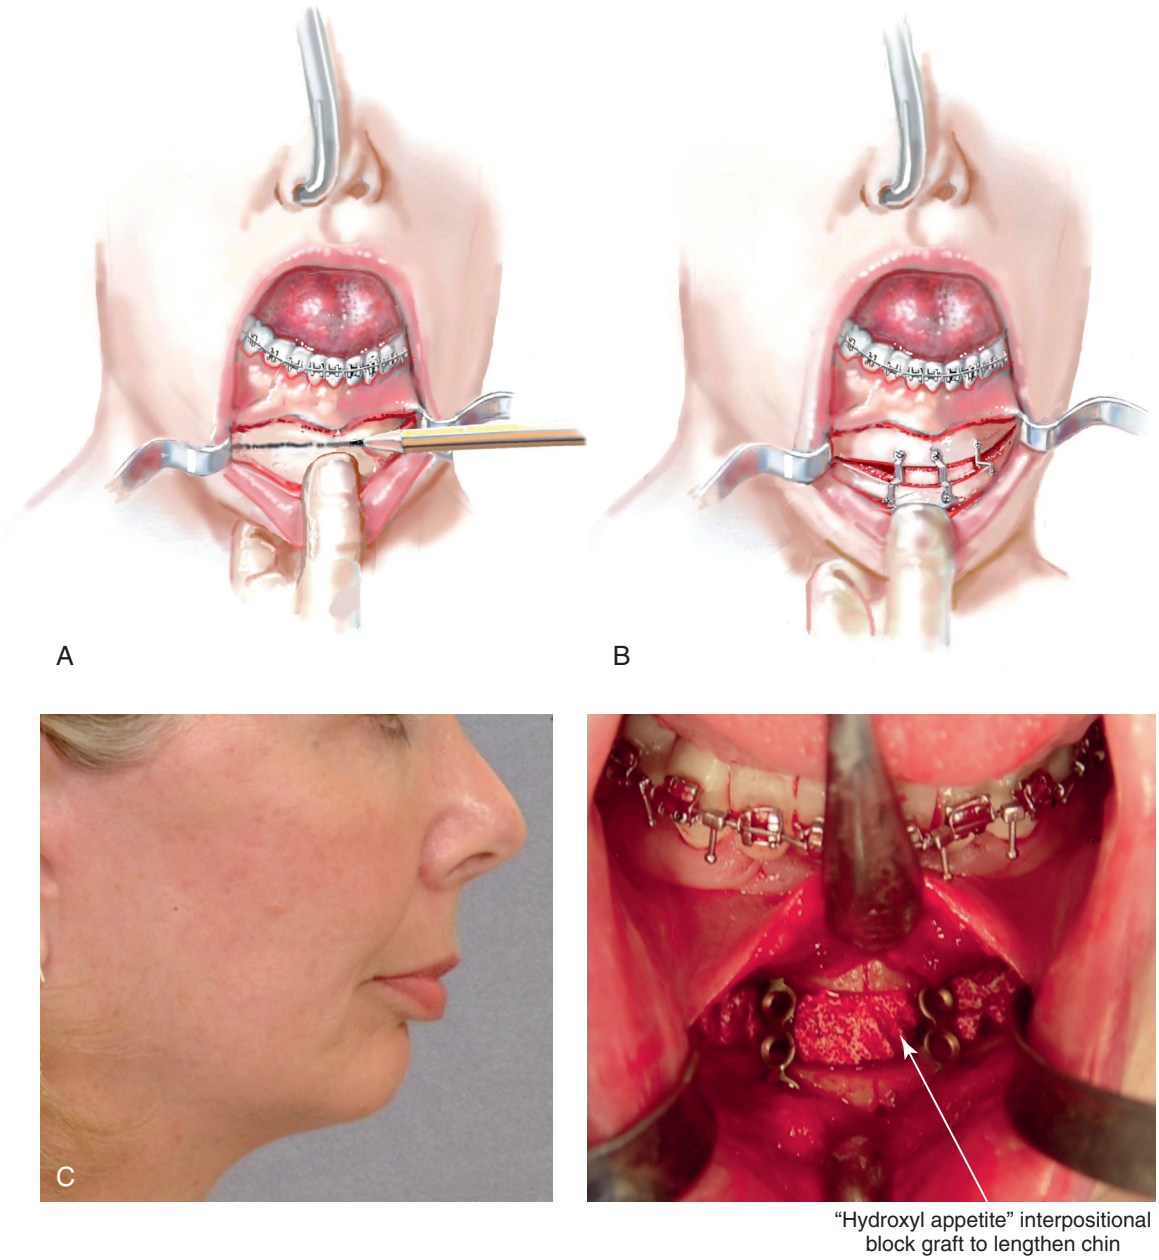
- The patient may shower without concern about moisture on the occlusive dressing that is covering the wound.
- The dressing remains intact for approximately 7 to 10 days.
- After the dressing is removed, no additional bandages are placed.

Alloplastic Graft (Porous Hydroxyapatite Bloc Implant)

When either a chin osteotomy with significant vertical lengthening or a Le Fort I osteotomy with significant horizontal advancement or vertical lengthening is carried out, an interpositional defect (i.e., dead space) is created. Despite rigid plate and screw fixation, inadequate bone contact across the osteotomy site may jeopardize successful healing (e.g., fibrous union) or leave the upper jaw or chin prone to skeletal relapse. When an interpositional graft is deemed necessary, I prefer to use either autogenous or allogenic anterior iliac crest. The disadvantage of an autogenous graft for this purpose relates to the potential for donor site morbidity. The use of porous bloc hydroxyapatite as an interpositional bone substitute in specific circumstances has been advocated by some.[11,18,27,30,87,93,94,98,95,97,129,134,139]

When bloc hydroxyapatite is used as an interpositional graft, histologic findings demonstrate fibrovascular and bone ingrowth into the interstices of the hydroxyapatite implants. Osteoid tissue is found in a diffuse fashion and interspersed between the calcified bone and the fibrous tissue. Osteoclastic activity is not demonstrated within the implanted bloc. Histologic examination of the bone–implant interface demonstrates no evidence of the resorption or remodeling of the bone. Medically packaged porous block hydroxyapatite is derived from specific marine corals that have a completely interconnected porous matrix with a pore size that averages 200 μm. The calcium carbonate skeleton is converted by the manufacturer to hydroxylated calcium phosphate. This mineral matrix is architecturally and chemically similar to the non-vascularized interstitial matrix of human cortical bone. Therefore, it provides a reasonable substitute scaffold for the potential ingrowth of fibrovascular tissue and bone. Unfortunately, the material has no intrinsic osteoinductive properties.

Coralline-derived porous bloc hydroxyapatite has been used successfully as an option when an interpositional graft is needed for chin-lengthening procedures (Fig. 18-6). Rosen and colleagues as well as other authors have published clinical reports of the use of this substance in the



• **Figure 18-6** In conjunction with an osseous genioplasty, if significant vertical lengthening is carried out, an interpositional graft (e.g., autograft, allograft, bloc hydroxyapatite) is crafted and placed in the gap. The graft fills the central gap in between the fixation plates. I do not find it necessary to place a graft in all of the lateral aspects of the gaps. An additional plate with screws is generally placed vertically in the midline across the osteotomy site directly over the graft. **A,** Illustration of a chin with vestibular incision exposure. The marking pencil indicates the proposed osteotomy. **B,** Illustration of osseous genioplasty with an interpositional graft. **C,** Profile view of a woman with a retrognathic mandible and a vertically short chin. Intraoperative view of the same patient indicating the completed osseous genioplasty with an interpositional hydroxyapatite graft.

Continued

• **Figure 18-6, cont'd D,** Profile views of the same patient shown before and after sagittal ramus osteotomies (horizontal advancement) and osseous genioplasty (vertical lengthening with interpositional hydroxyapatite graft). **E,** Oblique facial views before and after reconstruction (see Fig. 25-2).

above-mentioned manner with low rates of complications and rapid healing.[93-98] When used as an interpositional graft after Le Fort I osteotomy (as compared with at a chin osteotomy site), higher incidences of infection, sinus displacement, and extrusion have been reported and remain of concern.[139]

Allogenic (Human, Sterile, Freeze-Dried) Iliac (Corticocancellous Bloc) Graft

When either a chin osteotomy with significant vertical lengthening or a Le Fort I osteotomy with significant horizontal advancement or vertical lengthening is carried out, an interpositional defect (i.e., dead space) is created. Despite rigid plate and screw fixation, inadequate bone contact across the osteotomy site may jeopardize successful healing (e.g., fibrous union) or leave the upper jaw or chin prone to skeletal relapse. When an interpositional graft is deemed necessary, autogenous iliac bone offers theoretic wound-healing advantages, but it carries the potential for donor site morbidity. The use of allogenic iliac crest as an interpositional human bone substitute in these circumstances has been advocated and used successfully in clinical practice. With the use of current U.S. Food and Drug Administration and American Association of Tissue Banks standards and regulations, biomedical companies make sterile, freeze-dried, allogenic iliac crest bone available for use.

These sterile, freeze-dried allografts are processed from donated human tissue as a result of a gift from an individual or his or her family. The commercially available allografts

are generally processed with the use of patented and proprietary technology. The tissue is first disinfected and then terminally sterilized with the use of gamma radiation. The donor tissue should be screened and deemed suitable with reference to infectious disease test results, available donor medical history, and behavioral risks assessments. The physical assessment of the donor—including a review of relevant medical records and autopsy or coroner reports, if available—is preferred. Although few reports that critically evaluate the use of allogenic bone grafts specifically for orthognathic procedures are found in the literature, the successful use of these grafts for site-specific orthopedic procedures is well documented. In current clinical practice, when an interpositional graft is required at either the chin or the Le Fort I osteotomy site, I generally present both the autogenous and allogenic iliac crest graft options to the patient. If the patient is more than 50 years old or if he or she has hip, knee, or lumbar disc disease, I generally prefer the allogenic bone graft option. For a patient with a cleft maxilla that requires simultaneous fistula closure, I generally prefer autogenous bone. In most others circumstances, patient preference is a major factor.

Grafting Condyle and Ascending Ramus Defects

Autogenous Rib (Costochondral) Donor Site

When the condyle and portions of the ascending ramus have been removed (e.g., after tumor or trauma) or are congenitally absent (e.g., in a patient with hemifacial microsomia with Kaban type IIB malformation), there will be a limited number of reconstructive options to choose from, including an autogenous costochondral graft; an artificial total joint replacement; an autogenous vascularized fibular composite flap; or a sagittal split ramus osteotomy with proximal segment repositioning (see Chapters 27, 28, 35, and 36). For a patient who requires condyle and ascending ramus reconstruction, these options are not likely to give equivalent results. Clinical judgment and experience are required to assess the defect and the patient-specific factors (i.e., age, medical condition, quality of the recipient bed, and dental rehabilitation needs) before recommending the option that is best suited to the individual's reconstructive needs.

When a costochondral graft reconstruction is chosen, the harvesting of a portion of the sixth or seventh rib with a limited cartilaginous cap from the contralateral chest wall (of the recipient site) generally provides the best contour and morphology for the deficient mandible.

The use of an autogenous costochondral graft for the reconstruction of a deficient condyle and ascending ramus in an individual at or after skeletal maturity remains the author's preferred approach for patients with Kaban type IIB and type III mandibular malformation with hemifacial microsomia (see Chapter 28; Fig. 18-7). For a patient with a posttraumatic deformity (e.g., after condyle fracture), when the deficient condyle cannot be managed by the sagittal splitting the ramus of the mandible with proximal segment relocation into the glenoid fossa, then an autogenous costochondral graft is also generally the author's preferred approach (see Chapter 35). When the defect of the mandible or the glenoid fossa is more extensive and combined with soft-tissue hypoplasia or if the patient has undergone radiation therapy, then an autogenous vascularized crafted fibular composite flap is generally preferred (see Chapter 28). For an adult patient with a history of recurrent ankylosis, an artificial total joint replacement maybe the preferred recommendation.

Step-by-Step Approach

Preparation and Draping

- Nasotracheal intubation (i.e., RAE tube) is completed and secured in accordance with the patient's head and neck reconstruction needs.
- Ophthalmic ointment and corneal shields are placed for eye protection.
- The rib to be harvested is palpated and identified.
- Betadine solution is used for both chest wall and head and neck preparation.
- The patient is prepped below the rib cage, past the chest midline, superior to the nipple, and laterally to the midaxillary line.
- Draping is completed, with limited skin exposure left parallel to and on all sides of the planned incision.

Surgical Markings

- The planned incision (i.e., ≈4 cm) is located and marked with a surgical pen directly over the rib for harvesting before preparation and draping.

Local Anesthesia

- Xylocaine (1% with 1 : 100,000 epinephrine) is injected into the soft tissue below the planned incision and to the depth of the rib to be harvested.

Skin Incision and Flap Elevation

- With the use of a knife (no. 15 blade), the incision is carried through the skin, the subcutaneous tissue, the fascia, and the muscle directly over the rib to be harvested.
- Superior and inferior flaps are elevated to provide deep exposure of approximately 6 cm of bone and 2 cm of adjoining cartilage.

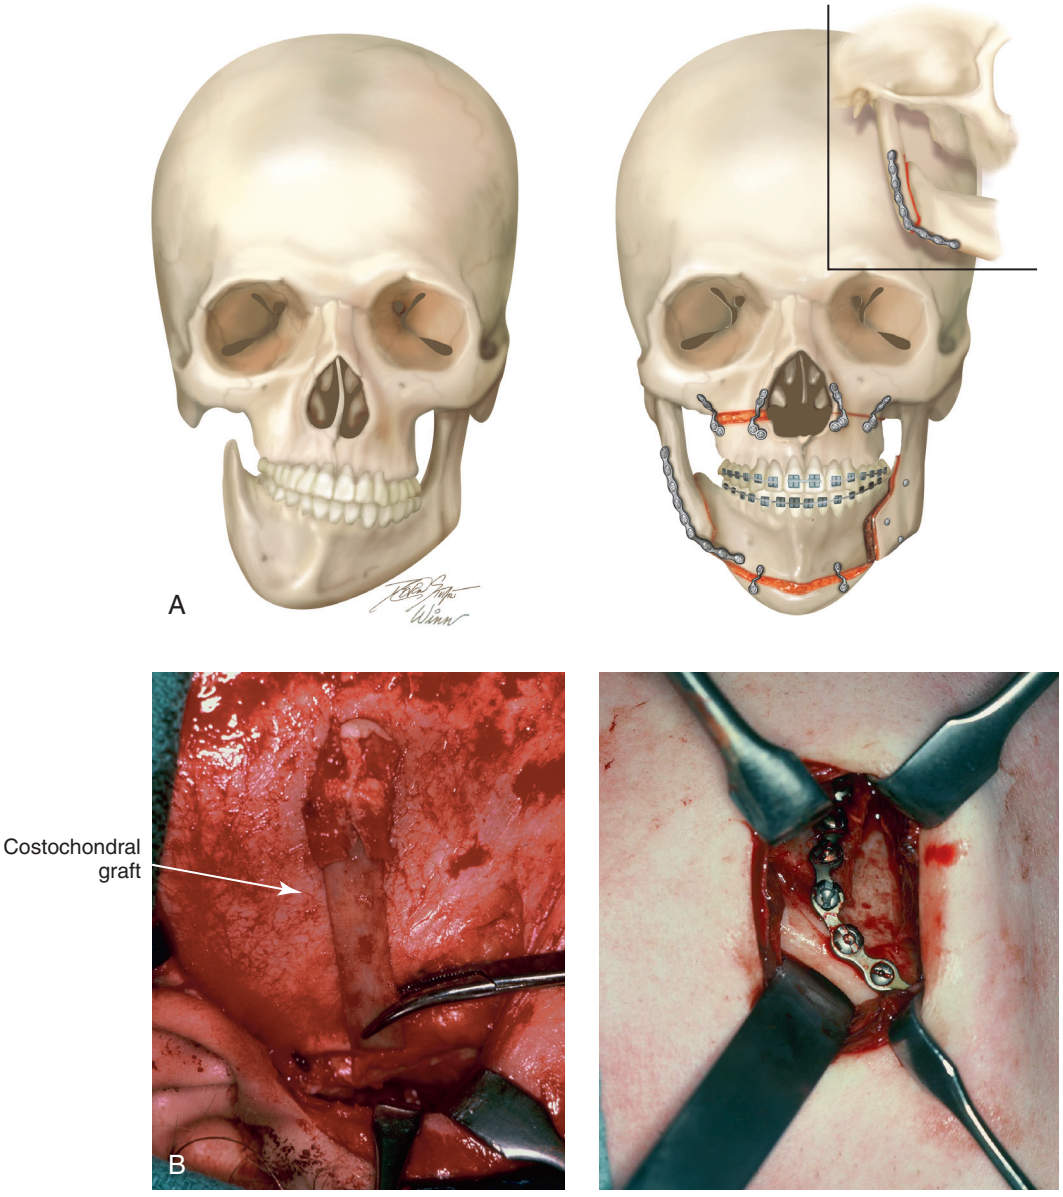
Graft Harvesting

- The periosteum is scored directly over the mid portion of the long axis of the rib to be harvested but not through bone or into the cartilaginous cap.
- Curved and straight elevators are used to dissect in the subperiosteal plane circumferentially around the rib to be harvested.

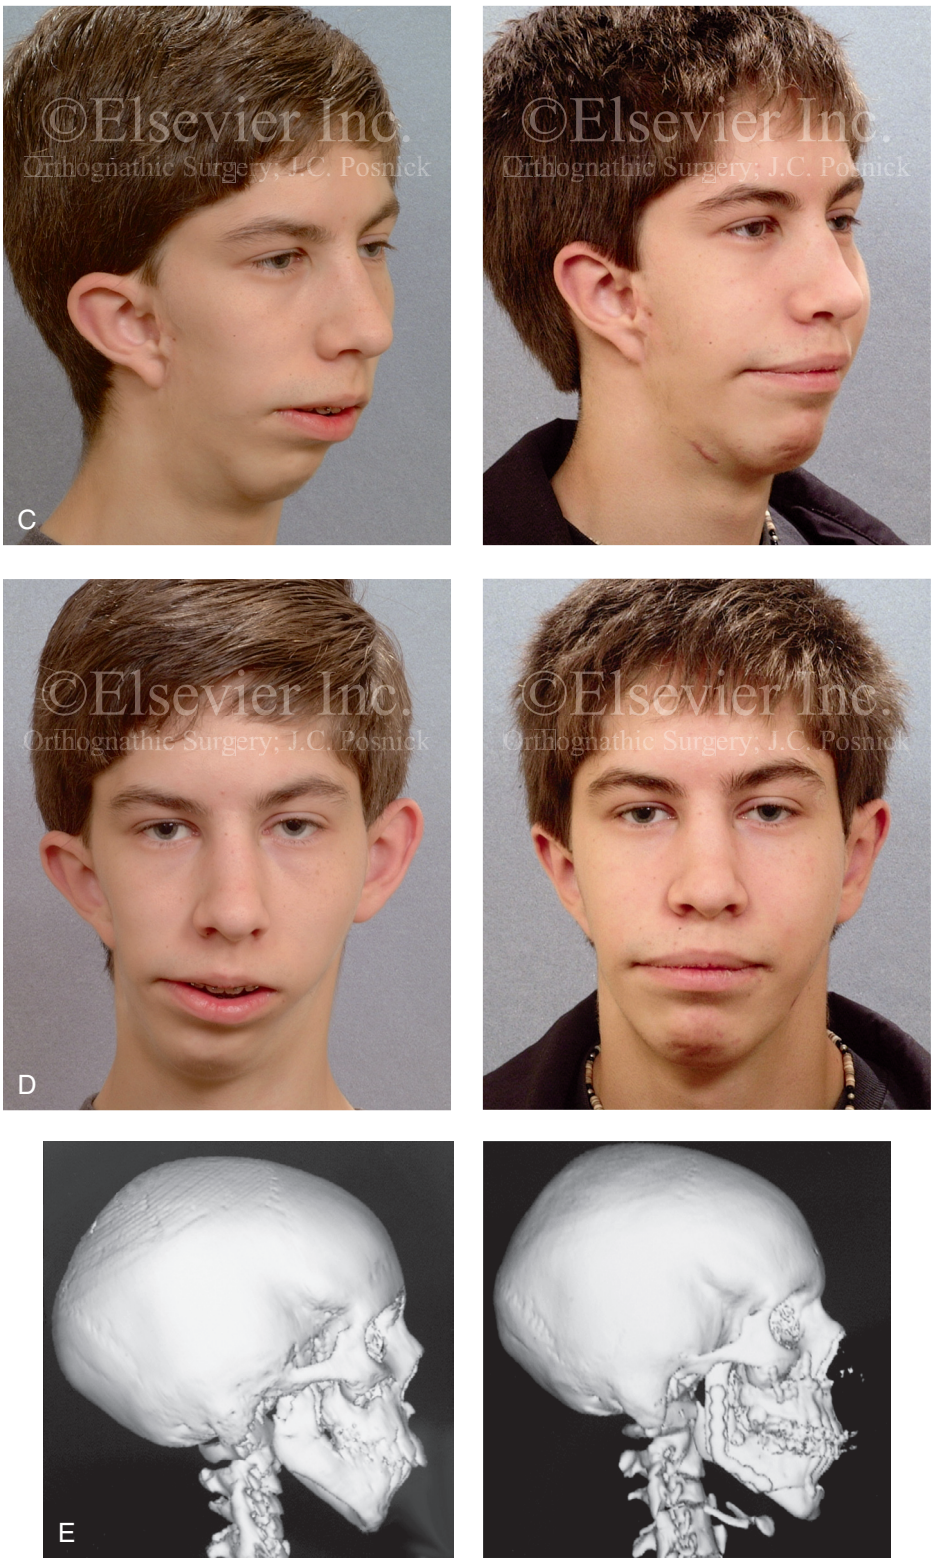
- A curved subperiosteal dissector (e.g., Doyen) is then inserted underneath and around the rib. This instrument is used to further strip and gain exposure in the subperiosteal plane, including underneath the cartilaginous cap.
- For protection, the retractor (e.g., Doyen) is placed deep and directly underneath the location for incising the cartilaginous cap.
- A knife (no. 15 blade) is then used to incise the full thickness of the cartilaginous cap, including not more than 1 cm of cartilage attached to the bone.
- The retractor (e.g., Doyen) is removed, and the rib cutter is inserted to cut and completely separate the rib according to the length of bone required for the purposes of reconstruction. The graft is removed.

Wound Closure

- The wound is checked for hemostasis and any exposure into the lung cavity; this is done by filling the wound with saline. The anesthesiologist introduces maximum end tidal volume and holds the area under pressure with the Valsalva maneuver. With the confirmation of no pneumothorax, wound closure is accomplished.
- The periosteal sleeve is approximated with interrupted suture ties (3-0 Vicryl).



• **Figure 18-7 A,** Illustrations of hemifacial microsomia (type IIB mandibular malformation) that show the presenting skeletal deformities and what the skull looks like after reconstruction is carried out. **B,** A patient has a costochondral graft inserted through a coronal (scalp) incision to reconstruct a condyle ascending ramus deficit. Stabilization of the graft occurs with an extended miniplate and screws placed through a Risdon (neck) incision. *Part A modified from an original illustration by Bill Winn.*



• **Figure 18-7, cont'd C,** Right oblique facial views of a teenaged boy with hemifacial microsomia (type IIB) before and after reconstruction. **D,** Frontal facial views before and after reconstruction. **E,** Profile computed tomography scan views of the same patient before and after reconstruction that demonstrate mandibular malformation and costochondral graft reconstruction.

- The deep and superficial fascia layers are closed with interrupted suture ties (3-0 Vicryl).
- Subdermal closure is performed with interrupted suture ties (4-0 Vicryl).
- The skin is closed with subcuticular running suture (5-0 resorbable).

Placement of Dressing

- The skin surface is cleaned with saline. It is then dried, and benzoin is applied.
- A limited number of Steri-Strips are placed directly over the closed wound.
- A small piece of cut gauze is placed directly over the Steri-Strips.
- An occlusive dressing (e.g., Tegaderm) is placed over the skin.

Postoperative Care

- A postoperative chest radiograph is used to confirm that there is no injury to the lungs.
- The patient may shower without concern about moisture on the occlusive dressing that is covering the wound.
- The dressing remains intact for approximately 7 to 10 days.
- When the dressing is removed, no additional bandages are placed.

Cartilage Grafting for Nasal Reconstruction

Over the last several decades of cosmetic rhinoplasty, the paradigm has shifted from aggressive reductive procedures to augmentation procedures. More attention is now focused on the use of grafts to augment deficiencies and the appropriateness of the graft material selected for each indication. When surgically altering the shape of the nose, two frequent reconstructive concerns are inadequate structural integrity and volume. These problems are generally best addressed with the use of cartilage grafts taken from a limited number of donor sources, such as the septum, the conchal bowl of the ear, or the rib cartilage. The choice of grafts and of the techniques used to place them remain both an art and science (see Chapter 38).[14,31]

Autogenous Nose (Septal) Cartilage Donor Site

Septal cartilage is generally reasonably straight and resilient; it provides structural support similar to that of the native nasocartilaginous framework. The septal cartilage can be contoured, carved, and sutured into an exact location. Significant resorption, infection, or warping is uncommon unless the cartilage is subjected to high-tension forces or crushing during preparation. Preferred uses for septal cartilage in nasal reconstruction often include caudal struts, lower lateral cartilage (LLC) crural grafts, spreader grafts, and tip grafts (e.g., shield grafts) to increase projection or definition (Fig. 18-8).[38,39]

A main disadvantage of the use of septal cartilage in nasal reconstruction is the limited amount that is often available. Anterior to the vomer and perpendicular plate of the ethmoid, septal cartilage can be harvested without concern, but always with the maintenance of the anterior structural support of the cartilaginous septum (i.e., adequate dorsal and caudal struts) to prevent dorsal or caudal collapse. In most individuals, unless the septal cartilage has been previously removed through submucous resection or is absent for other reasons (e.g., infection, congenital condition, ischemic necrosis), adequate cartilage can generally be harvested to serve as a caudal strut graft (i.e., to provide tip support); spreader grafts (i.e., to widen the nasal valves or to straighten the cartilaginous dorsum); LLC support (i.e., for the cleft or "pinched" nose); or as additional tip augmentation (see Chapters 29, 32, 33, 35, and 38).

Step-by-Step Approach (Fig. 18-9)

Preparation and Draping for Rhinoplasty

- Orotracheal intubation (i.e., RAE tube) is placed as required for the rhinoplasty procedure. The tube is taped to the chin to prevent dislodgement.
- Ophthalmic ointment and corneal shields are placed for eye protection.
- If the patient's hair is long, it is tied in a ponytail.
- Betadine solution is used for the preparation of the scalp, forehead, external ears, face, and neck. (Do not use soap, alcohol, Hibiclens, and so on.)

Draping is completed, with exposure of the forehead, the external ears, the face, and the neck down to the clavicles left in the operative field as per the routine for rhinoplasty.

Surgical Marking

The columella (stair-step) incision and the bilateral rim (marginal) intranasal incisions are located and marked with a surgical pen before prep and draping.

Local Anesthesia

- Xylocaine (1% with 1:100,000 epinephrine) is injected deep into the skin within the soft-tissue envelope of the nose as is routine for rhinoplasty.
- Xylocaine (1% with 1:100,000 epinephrine) is injected on each side of the septum, deep to the mucosa and superficial to the cartilage.
- Cocaine-soaked pledgets (5 cc of 4% solution) are placed in each nasal cavity.

Skin Incision and Flap Elevation

- The columella skin is incised, and the intranasal rim incisions are made.
- The nasal soft-tissue envelope is elevated with Stevens scissors as required for an open rhinoplasty procedure.

• **Figure 18-8 A,** Profile views of a teenaged girl before and after rhinoplasty with the use of a septal (caudal strut) cartilage graft to improve tip position and projection as described in Fig. 18-9. **B,** Oblique facial views before and after reconstruction.

Graft Harvesting

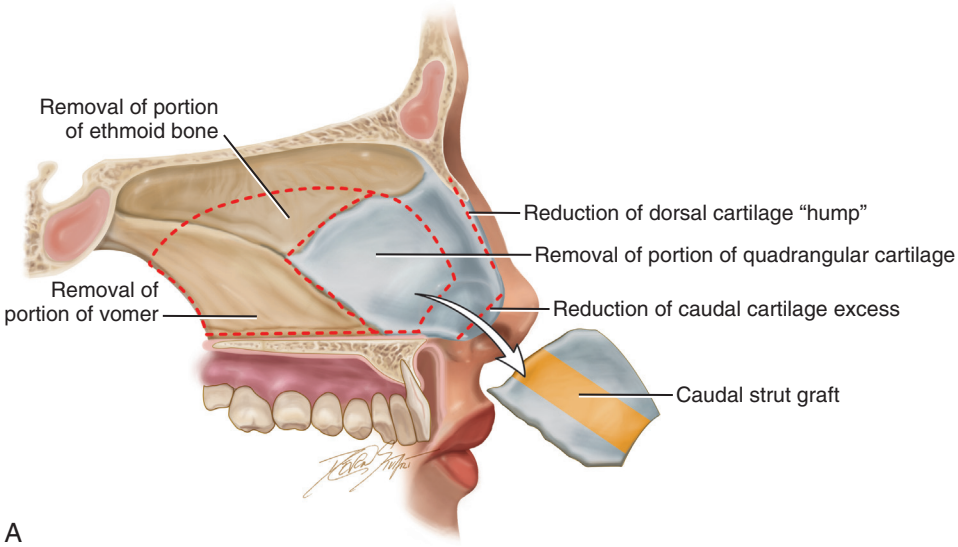
- Separate the lower lateral cartilages with Stevens scissors. Dissect down to and identify the anterior aspect of the caudal septal cartilage. Use a sharp periosteal elevator (e.g., Cottle) to initiate the submucosal dissection on each side of the caudal edge of the septal cartilage. Extend the submucosal dissection inferior to the maxilla and posterior to the vomer. Continue the subperiosteal dissection as required for the resection of the deviated bony septum.
- Use a knife (no. 15 blade) to initiate a caudal and dorsal septal incision through the quadrangular cartilage for the insertion of a swivel knife. The incision is located to maintain approximately 10 mm of caudal and 10 mm of dorsal septal cartilage.
- Insert the swivel knife, and incise the septal cartilage for graft harvesting and for submucous resection as indicated.
- Remove the incised septal cartilage graft.

Crafting of Graft

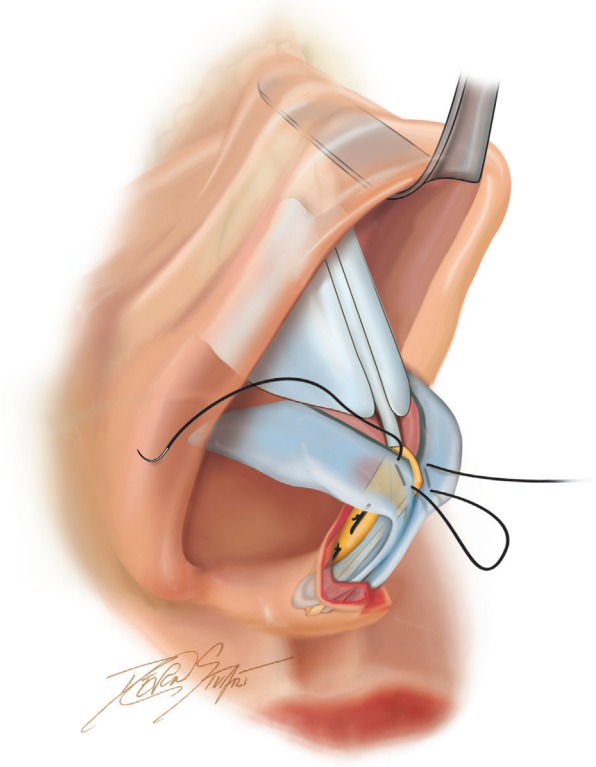
- Use a knife (no. 15 blade) to carve out and craft the required grafts (e.g., caudal strut, LLC reconstruction, spreader grafts, tip augmentation) from the full piece of harvested septal cartilage.

Wound Closure

- After the completion of the septorhinoplasty procedure, the closure of wounds is performed per routine rhinoplasty.

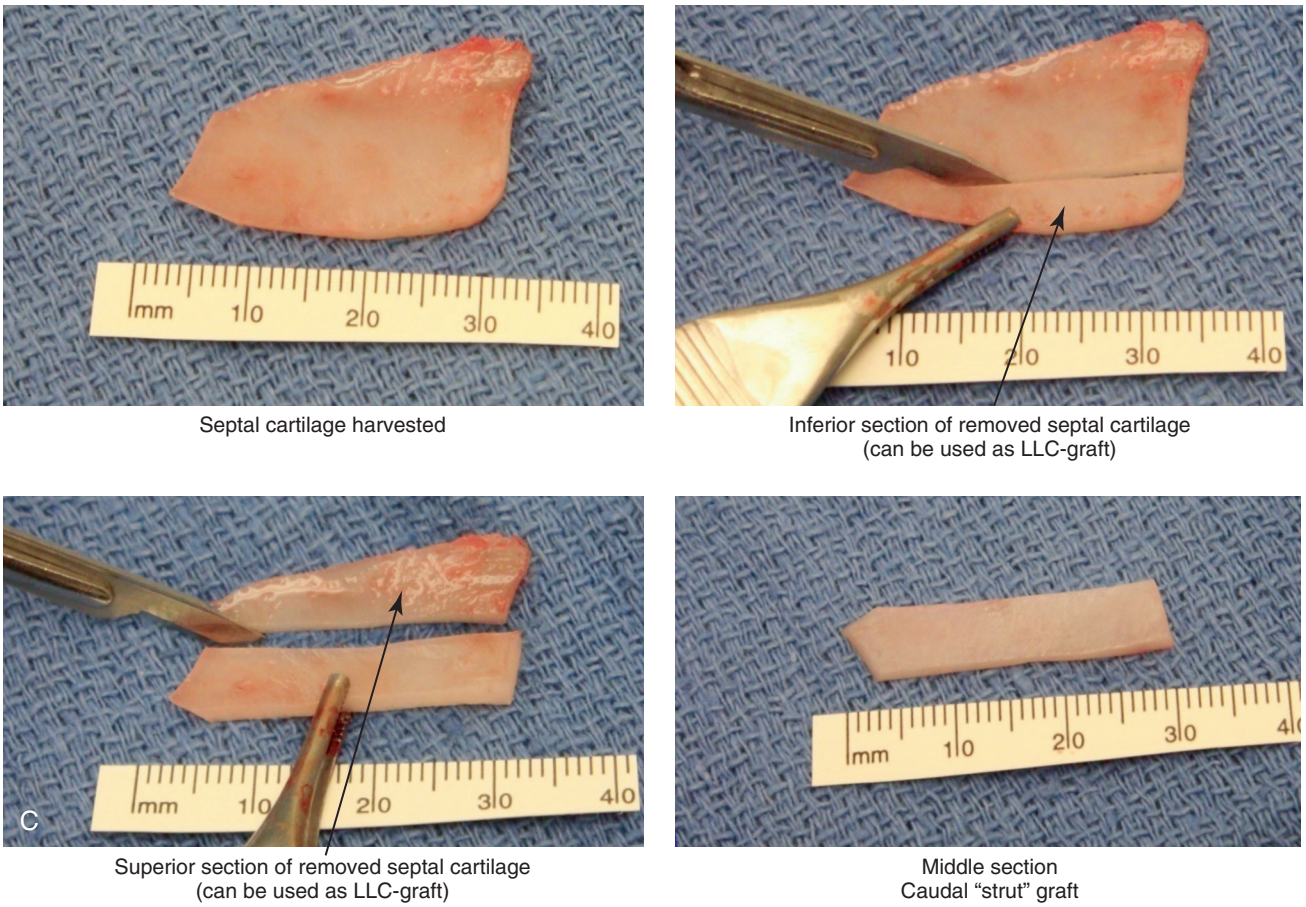


A



B Caudal strut graft sutured in place, lower lateral cartilages are then sutured together and over the top of the graft

• **Figure 18-9 A,** Illustrations that demonstrate the location of the harvesting of a septal cartilage graft and **B,** of the graft's placement as a caudal strut.



• **Figure 18-9, cont'd C,** Intraoperative views of removed septal cartilage that can be used for grafts to reconstruct the nose. The cartilage can be crafted as a caudal strut, spreader grafts, a lower lateral cartilage augmentation graft, and as tip onlay grafts.

- To approximate the columella skin (i.e., the stair-step incision), a single dermal suture is placed (5-0 Vicryl).
- Columella skin closure is performed with interrupted suture ties (6-0 nylon).
- Intranasal wound closure is performed with interrupted ties (5-0 chromic).

Placement of Dressing

- The placement of dressings is routine as per the septo-rhinoplasty procedure.
- Flexible splints (e.g., Reuter Type-Medtronic USA INC, Jacksonville, FL.) are generally placed on each side of the septum and secured together with a single suture tie (3-0 nylon).
- Antibiotic ointment (e.g., Bactroban) is generally injected into each nostril cavity.
- Packing (e.g., folded Telfa) is generally inserted equally into each nostril cavity.
- Tape (e.g., a Steri-Strip) is placed over dorsum of nose as per rhinoplasty procedure.
- A custom splint (e.g., Aquaplast) is molded over the dorsum of nose as per rhinoplasty.

Autogenous Ear (Conchal) Cartilage Donor Site

Conchal cartilage may be required for augmentation during secondary rhinoplasty when prior harvest, trauma, infection, or a genetic deficiency has rendered the nasal septal framework deficient and unavailable as a graft source.[76,79] In these cases, conchal cartilage may be the default option for non-structural nasal reconstruction applications. The conchal cartilage is pliable, resilient, flat, and thin. The conchal bowl may also have the natural contour to fit a specific nasal reconstructive need. Histologically, auricular cartilage is elastic hyaline. The flat base of the conchal bowl serves as the donor site and is harvested through a postauricular skin incision without leaving a noticeable aesthetic change in the external ear. The conchal bowl is composed of two components: the superior cymba and the inferior cavum. These are divided by the conchal extension of the helical root. The conchal bowl is bordered by the helical root and the external auditory meatus. Human anatomic dissection confirms the dimensions of the conchal bowl: it has a thickness of 1.9 mm to 4.4 mm; a maximum width of 1.9 cm to 2.9 cm; and a maximum height of 1.9 cm to

3.1 cm that can be harvested. During the harvesting of a conchal graft, the sidewalls are preserved to maintain the structural stability of the ear. A conchal graft can be useful for the reconstruction of the LLC (e.g., cleft nasal deformity, overresected iatrogenic deformity); spreader grafts (i.e., when minimal structural support is required); or nasal tip augmentation (i.e., when the underlying support is adequate). It is almost always a second or third donor site choice when nasal structural support is required, because it lacks sufficient strength to be used routinely as either a dorsum or caudal strut framework. In most cases, septal cartilage is preferred for these indications. For situations in which significant stretching of the overlying soft-tissue envelope is required to achieve tip projection (e.g., cocaine saddle deformity, bilateral cleft nasal deformity, Binder nasal deformity), a rib cartilage graft will best provide the needed framework support (see Chapters 29, 32, 33, 35, and 38).

Step-by-Step Approach

Preparation and Draping

- Orotracheal intubation (i.e., RAE tube) is placed as required for the rhinoplasty procedure. The RAE tube is taped to the chin to prevent dislodgement.
- Ophthalmic ointment and corneal shields are placed for eye protection.
- If the patient's hair is long, it is tied in a ponytail.
- Betadine solution is used for the preparation of the scalp, forehead, external ears, face, and neck. (Do not use soap, alcohol, Hibiclens, and so on.)
- Draping is completed, with exposure of the forehead, the external ears, the face, and the neck down to the clavicles left in the operative field as per the routine for rhinoplasty.

Surgical Marking

- The postauricular skin incision is located and marked with a surgical pen before preparation and draping.
- The incision is centered on the long axis of the ear from the superior helical rim to the lobe. Stop the incision approximately 1 cm short of the superior and inferior margins of the ear.

Local Anesthesia

- Xylocaine (1% with 1 : 100,000 epinephrine) is injected into the postauricular sulcus between the mastoid fascia and the ear cartilage.

Skin Incision and Flap Elevation

- With the use of a knife (no. 15 blade), the full thickness of the skin is incised along the surgical markings.
- Stevens scissors are used to elevate the medial postauricular flap. The incision is made on the surface of the postauricular cartilage and then down to the mastoid fascia.

Graft Harvesting

- The place at which the flat and curved portions of the conchal bowl meet is identified.
- The planned incision is marked to follow the natural curve of the conchal cartilage at the location at which the flat bowl begins.
- With a fresh knife (no. 15 blade), the full thickness of the conchal cartilage is incised at the surgical marking, without perforation through the anterior skin.
- With the use of a sharp periosteal elevator (e.g., Cottle), the incised cartilage is freed from the tightly attached overlying anterior skin along the flat portion of the conchal bowl.
- A decision about the volume of the conchal cartilage graft required is made.
- The conchal bowl is incised at the desired location to achieve graft requirements.
- Hemostasis and the integrity of the anterior auricular skin are confirmed.

Wound Closure

- Several interrupted sutures and then running and locking resorbable sutures are placed for skin closure (5-0 chromic). This prevents the need for postoperative suture removal.

Placement of Dressing

- A thick coat of antibiotic ointment is placed in the postauricular fold and over the anterior ear skin surface.
- A sheet of gauze (e.g., Xeroform) is placed in the postauricular groove and also on the anterior skin surface.
- Two or three pieces of dry "fluff" gauze are placed over the anterior surface of the ear.
- Gauze rolls (e.g., Kerlix) are used as a wrap to hold the fluff gauze and to apply gentle pressure. The gauze dressing is looped around the anterior neck and the forehead to secure it.
- An Ace wrap is loosely placed as an outer layer of the head and ear dressing.
- The whole dressing is removed without replacement 5 to 7 days later.

Postoperative Care

- After the ear dressing is removed, the patient is encouraged to shower and shampoo the hair, the external ears, the face, and the neck once or twice daily as per the rhinoplasty routine.
- The donor ear is dabbed dry (i.e., not rubbed) after washing.
- No vigorous sports activities are allowed during the early phase of healing (i.e., approximately 4 to 6 weeks) as per rhinoplasty.

Autogenous Rib (Cartilage Only) Donor Site (Video 10)

When significant structural support is required for either the caudal septum or dorsum of the nose within a tight soft-tissue envelope, neither conchal nor septal cartilage will generally be adequate. In these cases, autogenous rib

cartilage will frequently be the graft material of choice (Fig. 18-10) (see Chapters 29, 32, 33, 35, and 38).[37,59,68,84-86,108,109] Costal cartilage is available in abundance, it undergoes minimal postoperative resorption, and it is relatively easy to carve into a strut graft. Its perceived donor site harvesting difficulties often dissuade surgeons from choosing it; these include the need for a small scar on the anterior lower chest wall as well as concerns about pneumothorax and postoperative pain. With meticulous surgical technique, these potential disadvantages are generally overcome. However, somewhat unpredictable occasional graft warping that may jeopardize the long-term aesthetic results when used as either a dorsal or caudal strut remains a concern. Gibson's experimental studies provide the principles for understanding and managing cartilage warping.[31] He suggested the use of "balancing cross sectional carving along the long axis of the cartilage as a way to limit/prevent warping." The general approach when carving costal cartilage involves symmetrical removal from both sides and then using the central core of the cartilage for reconstruction and augmentation whenever feasible. In vitro studies suggest that the full distortion of the graft may be demonstrated within 30 minutes of carving. At a minimum, using Gibson's balanced carving principles and waiting 15 minutes before graft placement are likely to uncover warping tendencies in a majority of cases. We often use internal stabilization of the dorsal strut (and, less often, of the caudal strut) via the placement of a Kirschner wire (K-wire; no. 35

• **Figure 18-10** Facial views of a teenager who was born with unilateral cleft lip and palate before and after cleft jaw reconstruction followed by cleft rhinoplasty. The nasal reconstruction involved the use of a rib cartilage (caudal strut) graft as described in Figure 18-11. **A,** Profile facial views before and after reconstruction. **B,** Oblique facial views before and after reconstruction.

threaded) through the spine of the graft (see Chapters 29, 35, and 38).

Definitive rhinoplasty will be required for the reconstruction of the residual bilateral cleft lip nasal deformity at some point after the early teenage years. A "short" columella generally defines the presenting nasal deformity in the individual with bilateral cleft lip and palate (see Chapter 33). A crafted autogenous rib cartilage caudal strut provides the structural support to adequately stretch the columella skin and the soft-tissue envelope for favorable tip projection (see Fig. 18-10). The graft is stabilized to the base of the maxilla with a short, buried K-wire (no. 35 threaded). The LLCs are then sutured together over the top of the rib cartilage caudal strut to form the most superficial aspect of the tip (see Chapter 38).

For the reconstruction of the severe posttraumatic or congenital saddle nose deformity, rib cartilage often has advantages as compared with bone in that it restores at least a degree of springiness to the cartilaginous vault and tip; it is considered easier and less morbid to harvest; and it is not prone to resorption (see Chapter 35). A rib cartilage dorsal strut may extend from the radix to the nasal tip or just from the inferior aspect of the nasal bones to the tip. A K-wire may be inserted through the spine of the dorsal strut to prevent warping; this is done before graft inset. The dorsal strut is combined with a separate rib cartilage caudal strut, which extends from the base of the maxilla to the tip. A short buried K-wire secures the caudal strut to the base of the maxilla. The two grafts are then sutured together to form the new tip. The LLCs are sutured together and then over the top of the grafts to establish the most superficial aspect of the tip (see Chapter 38). The soft-tissue envelope is redraped over the reconstructed cartilaginous vault and tip.

For the correction of the cocaine-induced or iatrogenic saddle deformity of the nose, a rib cartilage graft is typically crafted into two struts (see Chapter 38). The first is a caudal strut that extends from the base of the maxilla to the new nasal tip. Assuming adequate height of the nasal bones (i.e., the osseous vault), the second graft (i.e., the dorsal strut) is inset deep and then flush with the bony dorsum. The dorsal strut extends to the new nasal tip. Each cartilage graft is secured in place at its point of insertion, and the grafts are then sutured to each other where they join at the tip. The LLCs are sutured together and then over the top of the grafts to form the most superficial aspect of the tip (see Fig. 18-9). The soft-tissue envelope is redraped over the reconstructed cartilaginous vault and tip (see Chapter 38).

Step-by-Step Approach (Fig. 18-11)

Preparation and Draping

- Orotracheal intubation (i.e., RAE tube) is placed as required for the rhinoplasty procedure. The RAE tube is taped to the chin to prevent dislodgement.
- The specific rib to be harvested is palpated and identified.
- Betadine solution is used for the preparation of both the hip and the head and neck. (Do not use soap, alcohol, Hibiclens, and so on.)
- The patient is prepped below the rib cage, past the chest midline, superior to the nipple, and laterally to the midaxillary line.
- Draping is completed, with limited skin exposure left parallel to and on all sides of the planned incision.

Surgical Markings

- The planned incision (i.e., ≈4 cm) is located and marked with a surgical pen directly over the rib cartilage to be harvested before preparation and draping.

Local Anesthesia

- Xylocaine (1% with 1 : 100,000 epinephrine) is injected into the soft tissues below the planned incision and to the depth of the rib cartilage to be harvested.

Skin Incision and Flap Elevation

- With the use of a knife (no. 15 blade), the incision is carried through the skin, the subcutaneous tissue, and the fascia directly over the rib cartilage to be harvested.
- Superior and inferior flaps are elevated to provide access to the rib cartilage.
- This should provide exposure of approximately 4 cm of rib cartilage.

Graft Harvesting

- The perichondrium is scored directly over the mid portion of the long axis of the rib cartilage to be harvested.
- Curved and straight elevators are used to dissect in the subperichondrial plane circumferentially around the cartilage to be harvested.
- A curved subperichondrial dissector (e.g., Doyen) is inserted underneath and around the rib cartilage. This instrument is used to gain further exposure in the subperichondrial plane.
- A retractor (e.g., Doyen) is placed deep and directly underneath the location for the incising of the cartilage graft. A knife (no. 15 blade) is then used to incise the full thickness of the cartilage.
- The retractor (e.g., Doyen) is then repositioned just below the other end of the cartilage at the location for incision. The knife (no. 15 blade) is used to incise the cartilage.
- The cartilage graft is removed.

Wound Closure

- The wound is checked for hemostasis and any exposure into the lung cavity; this is done by filling the wound with saline. The anesthesiologist introduces maximum end tidal volume and holds the area under pressure with the Valsalva maneuver. With the confirmation of no pneumothorax, wound closure is accomplished.
